Preface

Philosophy. The *Comprehensive Textbook of Psychiatry* has emerged from our experiences in establishing an undergraduate and graduate program in psychiatry. The responsibility for teaching students psychiatry has made us acutely conscious of the expansion of the field, of the many relevant additions to the traditional corpus of the discipline. Recent progress in psychiatry has come about not only as a result of the continuing search for etiologies, but also because of the flexibility afforded by new treatment modalities in a variety of settings.

The underpinnings of clinical psychiatry have increased both in number and in strength; the practitioner now has at his disposal large amounts of new knowledge in three major areas of behavioral science which must be incorporated within the existing theoretical and therapeutic knowledge in psychiatry. These three areas are the basic sciences, such as neurophysiology and neuropharmacology; those social sciences which deal with individuals; and those which deal with the behavior of groups and of systems. Knowledge in those fields is not to be viewed as a kind of intellectual veneer to cover over the student's rough edges. It is in fact a prerequisite for clinical competence. The perplexing array of drugs, for example, not only invites comprehension of their mode of action on the central nervous system; it demands such understanding to obviate the mechanical dispensing of preparations in the manner of a tradesman.

Similarly, the increasing awareness of the contribution of social factors to the development as well as the maintenance of mental illness calls for systematic training of the student in relevant aspects of the social sciences. The interplay between individual and social structure is especially important in disorders like addiction, alcoholism, delinquency, and educational disabilities, problem areas that psychiatry can no longer avoid.

While the limits of concern for psychiatry are not yet fixed or clear, the extension of the boundaries is reflected in such events as the passage of the Community Mental Health Centers Act of 1963, which mandates an increasing involvement by the mental health professions in the milieu of the patient in addition to the traditional focus on the individual and his family. Moreover, implementation of the Act requires some insight into the political process of the stated goal if comprehensive care is to be achieved.

Thus, modern psychiatric practice can develop only along the lines of a model sufficiently complex to allow

for new inputs and sufficiently flexible to adapt to a rapidly changing social scene. Such a model should at least take into account certain features of American life that distinguish it from that in other highly developed countries.

The organizing principles for this textbook are derived from certain distinctive characteristics of American life that are rooted in our history and form the guidelines for the development of our social institutions. The first of these is *pluralism*. American communities are composed of a multitude of governmental structures and private groups, each with a measure of power and strength, sometimes cooperating, but often acting competitively. Each has its own responsibilities out of whose fulfillment arises still more diffuse goals. The operations of such groups are seldom conducive to the formation of unified conceptual systems, and the history of American psychiatric schools is no exception to this rule. To present this diversity in all its richness and contradiction, it is necessary to be truly eclectic. It has been our aim in this volume to include all the major contributions and trends that are now influencing the directions of the field. The genesis of this diversity is based not only on the steady growth of knowledge within the United States but also the constant enrichment of American intellectual life through immigration. New ideas brought here by our colleagues from abroad have taken root and flourished. Many such notions are now incorporated in the body of American psychiatry, which has been in this way enhanced immeasurably.

If pluralism is a feature of American life that demands recognition, *pragmatism* is one requiring compensation. While truth needs testing by the practical consequences of belief, everyday American pragmatism often goes beyond empiricism to a disregard for theory. Thus, American psychiatry has shown strength in the development and application of treatment methods while neglecting nosology and clinical description. Nosology is of relatively minor interest when psychiatric therapies are nonspecific; and indeed classification is not of practical use for those who are wedded to single general purpose therapies. To compensate for these weaknesses, we have stressed the development of theoretical models, the presentation of adequate clinical description, and the importance of classification schemes. To the same end, we have emphasized the behavioral science materials the full comprehension of which is required not only for practice but for expansion of theoretical understanding.

Where more traditional societies have revered what is old, Americans are typically engaged only by what is new. What amounts to a *veneration for change* gives rise not only to built-in obsolescence in a technological sense but also to a kind of galloping faddism in intellectual life. We have attempted to deal with this problem conservatively by preserving significant knowledge developed over time while presenting new approaches, not only to treatment but also to theoretical issues that are not immediately translated into therapeutic technique.

The fascination exercised by change results in a kind of *accretion* of ideas parallel to the proliferation of groups and structures. New hypotheses and treatment methods spread before older ones have been either validated or discarded. The coexistence of these notions necessitates their presentation even at the risk of cluttering. American psychiatry cannot be presented adequately in a simple statement. To oversimplify what is complex would be a disservice to the student and a backward step in the field. Hopefully, a comprehensive textbook of psychiatry can serve as an organizing statement for the multitude of relevant variables and as a first approach to what must be a complex model. More parsimonious statements must await further research and developments in the field. In the meantime, the premature closure of any aspect of psychiatry should be avoided and the evaluation of methods constantly encouraged.

Implementation. The organization and orientation of this book were determined, in large measure, by our assessment of the distinctive characteristics of modern American psychiatry and philosophy as expressed above. In addition, our efforts were guided by certain practical considerations. As a manual of instruction, the prescribed aim of this textbook is to foster professional competence. Accordingly, the content of this volume follows the psychiatric curriculum recommendations of the National Board of Medical Examiners and the American Board of Psychiatry and Neurology. On the other hand, presentation of the data which were noted earlier as essential to competence in this field was subject to certain restrictions, imposed by limitations of time and space.

In brief, in order to translate our ideals into the reality of a textbook, many practical problems had to be resolved and this, in turn, required some basic decisions. Specifically, it was decided (1) that the text would be multi-authored; (2) that the approach would be eclectic and multidisciplinary; and (3) that the book would be comprehensive in scope; i.e., it would include contributions on topics fundamental to psychiatry in addition to the traditional clinical material.

Authorship. A book written by a single author or by a few collaborators has certain indisputable advantages. Unity and continuity of text and consistency of viewpoint are thereby assured. On the other hand, while it may have been possible for a single Renaissance

man to acquire all the scientific knowledge accumulated in the Western world of his day so that he was qualified to write a comprehensive text on a specific subject, clearly this is no longer possible. Similarly, in psychiatry too, we seem to have passed, irrevocably, that point in time when a single individual could assimilate all the information necessary to write a textbook which covered the relevant material in sufficient depth to be of value to the serious student. We decided, because of these considerations, to follow the model of the great textbooks in clinical medicine and ask many authors to contribute to this textbook.

More specifically, invitations to participate in this book were directed to those authors who had made an original contribution to a particular aspect of psychiatry and who are acknowledged experts in that phase of theory or practice. We sought thereby to attain an authoritative and original approach to each area covered in the text. Viewed from this perspective, the use of multiple contributors appears to represent a solution to the problems created by the rapid expansion of knowledge in psychiatry. However, despite the advantages, this approach carried with it the potential danger that we might produce a loose collection of overlapping and discordant papers, rather than the integrated, unified textbook which was our goal. We attempted to deal with this problem in various ways. For one, we exerted editorial control by asking our collaborators to follow a specific outline in preparing their contributions. By so doing, we hoped to retain each author's unique, creative approach but at the same time ensure that each contribution formed an integrated part of a single text. This procedure was followed throughout, but, for obvious reasons, our task was more difficult—and, perhaps, our efforts less successful—in some areas of the volume than in others.

We used two other devices to achieve unification of this multi-authored venture: introductory statements by the editors appear at the beginning of each major area in the book, and a list of suggested cross references appears at the end of each section. The editors' introductions consist of a general statement of the current status of the specific topic under consideration, and a résumé of the contributions included within that area, with particular emphasis on the diversity in viewpoint. The suggested cross references attempt to guide the reader to relevant, related, and contrasting viewpoints presented in other parts of the book. It is hoped that this device will prove particularly helpful when the reader is faced with the difficult problem of correlating data derived from the basic behavioral sciences with clinical material.

Eclectic orientation. As mentioned above, we feel that psychiatry is currently in a state of rapid development and change. Therefore, commitment to any one approach would be unwise at this time and, in our opinion, would constitute a disservice to the discipline and to the young student who bears the

responsibility for its future progress. To preclude any tendency toward premature closure, authors committed to different theoretical models or schools of thought, as well as experts from various related disciplines such as neurophysiology, psychology, and sociology, were invited to contribute to the textbook and to present their respective approaches in depth. In the editors' introductions, we have discussed the value and potential power of each theoretical model and have indicated, when relevant, in the suggested cross references, the existence of alternate hypotheses.

We have tried to pursue this eclectic orientation throughout the volume, although our approach has varied, depending on the material under consideration. For example, in that part of the book which deals with the fundamental topics, the various theoretical models and disciplines stand side by side, and their very juxtaposition transmits the message of eclecticism. In the areas on clinical material each contributor can, of course, be expected to discuss the dynamics and treatment of a given disorder from the perspective of his particular theoretical orientation. In addition, however, in each instance the contributor has been asked to specify the existence of alternate approaches and assumptions.

Comprehensive scope. Again, we feel that psychiatry can no longer be taught as a "technical trade." Obviously, clinical competence is an essential goal of training, but it is not the only goal. As stated earlier, knowledge of the behavioral sciences and of underlying theoretical models is fundamental to theoretical understanding and clinical skills in psychiatry. Moreover, psychiatry is currently faced with the challenge of distributing its services to hitherto unreached populations. Therefore, in addition to clinical material on the description and treatment of the various disorders which constitute the content of the traditional psychiatric text, this book includes relevant biological, psychological, and sociological material, presentations of current concepts and theoretical models, and discussions of various aspects of community psychiatry.

Organization. The volume has been organized into eleven *areas* which deal with three basic aspects of the field of psychiatry—fundamentals, clinical issues, and related topics.

The first part of the book is concerned with fundamental aspects of psychiatry: thus, Area A contains a discussion of the history of psychiatry. In Area B, which deals with the basic behavioral sciences, the physiological, psychological, and social determinants of behavior are discussed by experts in these fields. An attempt was made to emphasize the relevance of these data for psychiatry. However, inclusion of an area on the basic behavioral sciences in a textbook of psychiatry is an innovation which is not without risk: while the material has great potential, and theoretical and practical value, some of it has not yet been explicitly assimilated into the main body of psychiatric knowl-

edge. The danger of including nonintegrated or seemingly irrelevant material, in terms of the confusion which this might engender, posed many difficult editorial problems.

Area C, on current concepts of personality and psychopathology, also deals with a fundamental aspect of psychiatry—the basic theoretical model. And Area C also represents an innovation in a psychiatric text in that it contains sections written by leading proponents of the various schools of thought whose concepts are part of the mainstream of current psychiatry. For the sake of comparison and uniformity, each contributor to Area C was asked to present the basic concepts of his model, as well as assumptions regarding the structure and development of normal personality, the determinants of various forms of psychopathology, and the implications for treatment of the theory to which he subscribed.

The clinical aspects of psychiatry comprise the major part of the text. Area D focuses on those aspects of neurology which have special relevance for psychiatry. Area E, on assessment in psychiatry, includes sections on the psychiatric examination, as well as on ancillary diagnostic procedures such as the psychological evaluation. In addition, Area E contains a chapter devoted to discussion of the cardinal manifestations of psychiatric disorders. Psychiatric symptoms are described therein with reference to specific diagnostic syndromes, in order to present these to the student in detail and at the same time obviate the need for their repeated description in connection with the discussion of each specific disorder. Essentially, Area F, which deals with the psychiatric disorders of adults, has been organized according to the *Standard Nomenclature* of the American Psychiatric Association. However, problems inherent in the current nosology are emphasized, and several topics which are not listed in the official system are discussed in this area. These include psychiatric emergencies, including suicide, as well as the unusual psychiatric syndromes that are seen in exotic cultural settings. The various forms of psychiatric treatment—psychological, organic, and milieu therapy—are dealt with in Area G. Child psychiatry has received extensive coverage in Area H, to the degree that we have attempted, in a sense, to organize a textbook within a textbook. The detailed treatment of this subspecialty reflects our conviction that this field will assume increasing importance in the near future.

The psychiatric subspecialties are covered in Area I, on community psychiatry, and in Area J, which deals with forensic psychiatry, geriatric psychiatry, military psychiatry, and industrial psychiatry. Finally, Area K covers fields related to psychiatry and includes chapters on clinical psychology, psychiatric social work, and psychiatric nursing.

Format. For many reasons, we decided to keep the text within the confines of a single volume. In view of the massive amount of data which had to be pre-

sented, this decision necessitated careful selection of material to be included and stringent limitations on the length of each contribution; and, finally, it became evident that if we wanted to include all the material which appeared to be important, we would be forced to resort to certain space-saving measures. One such measure was to limit the bibliography appended to each section, so that it contained mainly basic references to classic contributions in the literature. In addition, in order to retain all the important content of some of the longer sections, at times we found it necessary to print some portions of the material in smaller type. Admittedly, the use of "extract" type is not an ideal solution; however, no better alternative seemed to be available.

We have devoted four years to the preparation of this text, and it has been a deeply meaningful experience. The interaction with our distinguished and creative colleagues has been most gratifying, not only because it provided a unique opportunity to engage in a stimulating interchange of ideas on many levels, but

because of the rewarding personal relationships we have established.

We have received dedicated and valuable help from many people to whom we wish to express our deep appreciation. Of these, we would mention, in particular, Daniel Berson, Elizabeth Berson, Elaine Cohen, Nancy O'Shea, Irvin B. Schwartz, and Joan C. Welsh, who all played an especially important role in assisting us in our editorial and production work. In addition, we wish to thank Ann Cohen, Frieda Greer, Arthur Lohman, Carol Rodman, Ruth Van Buskirk, and Arthur Uhlman for their untiring efforts. Our publisher, Williams and Wilkins, has been very cooperative and we have appreciated the help of members of their editorial staff—James Gallagher, Dick Hoover, Mary Hutchinson, and James L. Sangston.

List of Contributors

Nathan W. Ackerman, M.D.

Clinical Professor of Psychiatry, Columbia University College of Physicians and Surgeons; Visiting Lecturer, Albert Einstein College of Medicine of Yeshiva University; Director of Professional Program, The Family Institute, New York, New York.

C. Knight Aldrich, M.D.

Professor of Psychiatry, University of Chicago School of Medicine; Attending Psychiatrist, University of Chicago Hospitals and Clinics, Chicago, Illinois.

Anne Anastasi, Ph.D.

Professor of Psychology, Fordham University Graduate School of Arts and Sciences, Bronx, New York.

E. James Anthony, M.D.

Ittleson Professor of Child Psychiatry and Director, Division of Child Psychiatry, Washington University School of Medicine; Training, Teaching, and Supervising Psychoanalyst, Chicago Institute for Psychoanalysis; Professorial Lecturer, University of Chicago School of Medicine, Chicago, Illinois; Physician, Barnes and Allied Hospitals, St. Louis, Missouri.

Arthur J. Bachrach, Ph.D.

Professor and Chairman, Department of Psychology, Arizona State University, Tempe, Arizona; Consultant in Neuropsychology, Barrow Neurological Institute, Phoenix, Arizona.

Arthur L. Benton, Ph.D.

Professor of Psychology and Neurology, University of Iowa, Iowa City, Iowa.

Irving N. Berlin, M.D.

Professor of Psychiatry and Pediatrics and Head, Division of Child Psychiatry, University of Washington School of Medicine, Seattle, Washington.

Irving Bieber, M.D.

Clinical Professor of Psychiatry, New York Medical College; Associate Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Associate Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Eugene L. Bliss, M.D.

Foundations Fund Professor of Psychiatry, Department of Psychiatry, University of Utah College of Medicine; Psychiatrist, University of Utah Medical Center, and Salt Lake City Veterans Administration Hospital, Salt Lake City, Utah.

C. H. Hardin Branch, M.D.

Professor and Chairman, Department of Psychiatry, University of Utah College of Medicine; Psychiatrist-in-Chief, University of Utah Medical Center; Consultant Psychiatrist, Salt Lake City Veterans Administration Hospital, Salt Lake City, Utah.

Henry Brill, M.D.

Professorial Lecturer, State University of New York Upstate Medical Center, Syracuse, New York; Lecturer, Columbia University College of Physicians and Surgeons; Clinical Professor of Psychiatry, New York School of Psychiatry, New York, New York; Director, Pilgrim State Hospital, West Brentwood, New York (on leave); Vice-Chairman, New York State Narcotic Addiction Control Commission, Albany, New York.

Norman Q. Brill, M.D.

Professor and Chairman, Department of Psychiatry, University of California School of Medicine at Los Angeles; Medical Director, Neuropsychiatric Institute, University of California Medical Center, Los Angeles, California.

Eugene B. Brody, M.D.

Professor and Chairman, Department of Psychiatry, University of Maryland School of Medicine; Director, The Psychiatric Institute, Baltimore, Maryland.

Henry W. Brosin, M.D.

Professor and Chairman, Department of Psychiatry, University of Pittsburgh School of Medicine; Director, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania.

Richard E. Brotman, Ph.D.

Professor of Psychiatry and Director, Division of Community Mental Health, New York Medical College, New York, New York.

Bertram S. Brown, M.D.

Assistant Clinical Professor of Psychiatry, George Washington University Medical School, Washington, D. C.; Deputy Director, National Institute of Mental Health; Assistant Surgeon General, United States Public Health Service, Bethesda, Maryland.

Fred Brown, Ph.D.

Professor of Psychiatry (Psychology), Mount Sinai School of Medicine; Head, Division of Psychology, Institute of Psychiatry, Mount Sinai Hospital, New York, New York.

Director of Clinical Investigations, National Institute of Mental Health, Bethesda, Maryland; Training and Supervising Psychoanalyst, Washington Psychoanalytic Institute, Washington, D. C.

Jonathan O. Cole, M.D.

Chief, Psychopharmacology Research Branch, National Institute of Mental Health, Bethesda, Maryland.

John J. Conger, Ph.D.

Vice-President for Medical Affairs and Dean, University of Colorado School of Medicine; Professor of Clinical Psychology, University of Colorado School of Medicine, Denver, Colorado.

Guido M. Crocetti, B.Sc.

Assistant Professor of Mental Hygiene, School of Hygiene and Public Health, Johns Hopkins University, Baltimore, Maryland.

Leon Cytryn, M.D.

Assistant Professor of Pediatric Psychiatry, George Washington University School of Medicine; Research Associate, Children's Hospital of the District of Columbia; Consulting Psychiatrist, Jewish Foundation for Retarded Children, Washington, D. C.

Allan J. D. Dale, M.D.

Consultant in Neurology, Mayo Clinic and Mayo Foundation, Mayo Graduate School of Medicine, University of Minnesota School of Medicine, Rochester, Minnesota.

Howard Davidman, M.D.

Assistant Dean and Professor of Psychiatry, New York School of Psychiatry, New York, New York.

John M. Davis, M.D.

Clinical Associate, Psychosomatic Section, Adult Psychiatry Branch, National Institute of Mental Health, Bethesda, Maryland.

Katrina de Hirsch, F.C.S.T., L.Sc.

Lecturer in Pediatrics, Columbia University College of Physicians and Surgeons; Director, Pediatric Language Disorders Clinic, Presbyterian Medical Center, New York, New York.

William C. Dement, M.D., Ph.D.

Associate Professor of Psychiatry and Head, Sleep Research Laboratories, Stanford University School of Medicine; Consultant in Psychiatry, Veterans Administration Hospital, Palo Alto, California.

Herman C. B. Denber, M.D., Ph.D.

Clinical Professor of Psychiatry, New York Medical College; Director of Psychiatric Research, Manhattan State Hospital; Associate Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Associate Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Cynthia P. Deutsch, Ph.D.

Senior Research Scientist, Institute for Developmental Studies, New York University School of Education, New York, New York.

Martin Deutsch, Ph.D.

Professor of Early Childhood Education, and Director, Institute for Developmental Studies, New York University School of Education, New York, New York.

Robert W. Doty, Ph.D.

Professor and Director, Center for Brain Research, and Professor, Department of Physiology, University of Rochester, Rochester, New York.

Leon Eisenberg, M.D.

Professor of Child Psychiatry, Johns Hopkins University School of Medicine; Psychiatrist-in-Charge, Children's Psychiatric Service, Johns Hopkins Hospital, Baltimore, Maryland.

George L. Engel, M.D.

Professor of Psychiatry and Professor of Medicine, University of Rochester School of Medicine and Dentistry; Psychiatrist and Physician, Strong Memorial Hospital, Rochester, New York.

W. D. Engels, M.D.

Lecturer in Psychiatry, McGill University School of Medicine; Assistant Psychiatrist, Royal Victoria Hospital, Montreal, Quebec, Canada.

Frank R. Ervin, M.D.

Assistant Professor of Psychiatry, Harvard Medical School; Director, Stanley Cobb Laboratories for Psychiatric Research; Psychiatrist, Massachusetts General Hospital; Consultant in Research, Boston State Hospital; Research Associate in Psychiatry, Boston City Hospital, Boston, Massachusetts.

Jack R. Ewalt, M.D.

Bullard Professor of Psychiatry, Harvard Medical School; Superintendent, Massachusetts Mental Health Center, Boston, Massachusetts.

Sol J. Ewen, D.D.S.

Assistant Clinical Professor of Periodontia and Oral Medicine, New York University College of Dentistry; Associate Clinical Professor of Dentistry, Mount Sinai School of Medicine; Associate Attending in Charge of Periodontia, Mount Sinai Hospital, New York, New York.

John A. Ewing, M.D.

Professor and Chairman, Department of Psychiatry, University of North Carolina School of Medicine; Chief of Psychiatry Service, North Carolina Memorial Hospital, Chapel Hill, North Carolina.

Stuart M. Finch, M.D.

Professor of Psychiatry, University of Michigan Medical School; Chief, Children's Psychiatric Service, Children's Psychiatric Hospital, University of Michigan Medical Center, Ann Arbor, Michigan.

Max Fink, M.D.

Professor of Psychiatry and Director of Clinical Services, Department of Psychiatry, New York Medical College; Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Visiting Psychiatrist, Metropolitan

Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Barbara Fish, M.D.

Associate Professor of Psychiatry, New York University School of Medicine; Psychiatrist-in-Charge, Child and Adolescent Psychiatry, Psychiatric Division, Bellevue Hospital, New York, New York.

Stephen Fleck, M.D.

Professor of Psychiatry and Public Health, Yale University School of Medicine; Psychiatrist-in-Chief, Yale Psychiatric Institute; Psychiatrist-in-Chief, Yale-New Haven Medical Center, New Haven, Connecticut; Consultant, Veterans Administration Hospital, West Haven, Connecticut; Consultant, Connecticut Valley Hospital, Middletown, Connecticut; Consultant, Family Service of New Haven, Inc., New Haven, Connecticut.

Donald H. Ford, Ph.D.

Associate Professor of Psychology and Dean, College of Human Development, Pennsylvania State University, University Park, Pennsylvania.

Hamilton Ford, Ph.D.

Professor and Chairman, Department of Neurology and Psychiatry, The University of Texas-Medical Branch; Psychiatrist-in-Chief, John Sealy Hospital and Affiliated University Hospitals, Galveston, Texas.

Jerome D. Frank, M.D., Ph.D.

Professor of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Shervert H. Frazier, M.D.

Professor and Chairman, Department of Psychiatry, Baylor University College of Medicine; Senior Attending Psychiatrist, Methodist Hospital; Consulting Psychiatrist, Rice University, Houston, Texas.

Alfred M. Freedman, M.D.

Professor of Psychiatry and Chairman of the Department of Psychiatry, New York Medical College; Director of Psychiatric Services, Flower and Fifth Avenue Hospitals, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Lawrence Z. Freedman, M.D.

Foundations' Fund Research Professor in Psychiatry, University of Chicago School of Medicine, Chicago, Illinois.

Marcia K. Freedman, Ph.D.

Research Social Scientist, Conservation of Human Resources, Columbia University, New York, New York.

Arnold P. Friedman, M.D.

Associate Clinical Professor of Neurology, Columbia University College of Physicians and Surgeons; Associate Attending Physician, Neurological Institute, Presbyterian Medical Center; Physician-in-Charge, Headache Unit, Division of Neurology, Montefiore Hospital and Medical Center, Bronx, New York.

Maurice R. Friend, M.D.

Clinical Professor of Psychiatry and Psychoanalytic Medicine, and Chairman, Education Committee, Division of Psychoanalytic Education, Department of Psychiatry, State University of New York Downstate Medical Center, Brooklyn, New York.

Herbert S. Gaskill, M.D.

Professor and Chairman, Department of Psychiatry, University of Colorado School of Medicine; Director of Psychiatric Services, University of Colorado Medical Center, Denver, Colorado.

Alvin I. Goldfarb, M.D.

Associate Professor of Psychiatry, New York School of Psychiatry; Associate Clinical Professor of Psychiatry, New York Medical College; Associate Clinical Professor of Psychiatry, Mount Sinai School of Medicine; Associate Attending Psychiatrist, Mount Sinai Hospital; Consultant on Psychiatric Services for the Aged, New York State Department of Mental Hygiene, New York, New York.

Milton Greenblatt, M.D.

Professor of Psychiatry, Tufts University School of Medicine; Lecturer in Psychiatry, Boston University School of Medicine; Lecturer in Psychiatry, Harvard Medical School; Superintendent, Boston State Hospital, Boston, Massachusetts.

Saul I. Harrison, M.D.

Professor of Psychiatry, University of Michigan Medical School; Director of Training, Children's Psychiatric Hospital, University of Michigan Medical Center; Supervising Psychoanalyst, Michigan Psychoanalytic Institute, Ann Arbor, Michigan.

Donald W. Hastings, M.D.

Professor and Chairman, Department of Psychiatry, University of Minnesota Medical School; Psychiatrist, University of Minnesota Hospitals, Minneapolis, Minnesota.

Herbert Hendin, M.D.

Associate in Psychiatry and Associate Psychoanalyst, Psychoanalytic Clinic for Training and Research, Columbia University College of Physicians and Surgeons; Associate Attending Psychiatrist, Harlem Hospital; Research Associate in Psychiatry, St. Luke's Hospital, New York, New York.

Eckhard H. Hess, Ph.D.

Professor and Chairman, Department of Psychology, University of Chicago, Chicago, Illinois.

Harold E. Himwich, M.D.

Clinical Professor of Neurology and Psychiatry, Stritch School of Medicine of Loyola University, Chicago, Illinois; Director, Research Division, Galesburg State Research Hospital, Galesburg, Illinois.

Williamina A. Himwich, Ph.D.

Professorial Lecturer, Stritch School of Medicine of Loyola University, Chicago, Illinois; Medical Research

Associate, Galesburg State Hospital, Galesburg, Illinois.

Ebbe C. Hoff, M.D., Ph.D.

Professor of Psychiatry and Chairman, Division of Psychiatric Research, Medical College of Virginia; Medical Director, Bureau of Alcohol Studies and Rehabilitation, Virginia State Department of Health, Richmond, Virginia.

Edward Hornick, M.D.

Associate Professor of Psychiatry, Albert Einstein College of Medicine of Yeshiva University; Chief of Psychiatric and Inpatient Service, and Senior Psychiatrist, Bronx Municipal Hospital Center, Bronx, New York.

Paul E. Huston, M.D., Ph.D.

Professor and Head, Department of Psychiatry, University of Iowa College of Medicine; Director, Iowa State Psychopathic Hospital; Director, Iowa Mental Health Authority, Iowa City, Iowa.

Turan M. Itil, M.D.

Associate Professor of Psychiatry, University of Missouri School of Medicine; Director, Department of Psychopharmacology, Missouri Institute of Psychiatry, University of Missouri School of Medicine, St. Louis, Missouri.

E. Roy John, Ph.D.

Research Professor of Psychiatry, and Director of Brain Research Laboratories, Department of Psychiatry, New York Medical College, New York, New York.

Lothar B. Kalinowsky, M.D.

Clinical Professor of Psychiatry, New York Medical College; Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home; Associate Professor of Neuropsychiatry, New York School of Psychiatry, New York, New York.

Leo Kanner, M.D.

Professor Emeritus of Child Psychiatry, Johns Hopkins University School of Medicine; Honorary Consultant, Johns Hopkins Hospital, Baltimore, Maryland.

Harold I. Kaplan, M.D.

Professor of Psychiatry and Director of Psychiatric Education and Training, New York Medical College; Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Helen S. Kaplan, M.D., Ph.D.

Assistant Professor of Psychiatry and Chief of Psychosomatic Medicine Service, New York Medical College; Assistant Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Assistant Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Stanley M. Kaplan, M.D.

Associate Professor of Psychiatry, University of Cincinnati College of Medicine; Attending Psychiatrist,

Clinician in Internal Medicine, and Associate Director, Psychosomatic Service, Cincinnati General Hospital, Cincinnati, Ohio.

Frederic T. Kapp, M.D.

Professor of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio; Training Psychoanalyst, Chicago Institute for Psychoanalysis, Chicago, Illinois; Attending Psychiatrist and Clinician in Psychiatry and Internal Medicine, Outpatient Department, Cincinnati General Hospital, Cincinnati, Ohio.

Stephen W. Kempster, M.D.

Assistant Professor of Psychiatry, Albert Einstein College of Medicine of Yeshiva University; Psychiatrist, The Family Institute; Attending Psychiatrist, Roosevelt Hospital, New York, New York.

Henriette R. Klein, M.D.

Clinical Professor of Psychiatry and Training Psychoanalyst, Psychoanalytic Clinic for Training and Research, Columbia University College of Physicians and Surgeons; Consulting Psychiatrist, St. Luke's Hospital Center, New York, New York.

Irvin A. Kraft, M.D.

Associate Professor of Psychiatry and Pediatrics, Baylor University College of Medicine; Medical Director, Texas Institute of Child Psychiatry; Chief of Psychiatry, Texas Children's Hospital, Houston, Texas.

Bernard Kramer, Ph.D.

Associate Professor of Preventive Medicine (Social Psychology), Tufts University School of Medicine; Staff Scientist, Boston Dispensary, Tufts-New England Medical Center, Boston, Massachusetts.

Maurice W. Laufer, M.D.

Member, Institute for the Health Sciences, Brown University; Adjunct Professor of Education, Rhode Island College, Providence, Rhode Island; Director, Emma Pendleton Bradley Hospital, Riverside, Rhode Island.

Ruth L. LaVietes, M.D.

Assistant Professor of Psychiatry, and Director of Child Psychiatry, New York Medical College; Assistant Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Assistant Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home; Instructor in Psychiatry, Psychoanalytic Clinic for Training and Research, Columbia University College of Physicians and Surgeons, New York, New York.

Heinz E. Lehmann, M.D.

Professor of Psychiatry, McGill University School of Medicine; Clinical Director and Director of Research, Douglas Hospital, Montreal, Quebec, Canada.

Alexander H. Leighton, M.D.

Professor of Social Psychiatry and Head of the Department of Behavioral Sciences, Harvard School of Public Health, Boston, Massachusetts.

ment of Behavioral Sciences, Harvard School of Public Health, Boston, Massachusetts.

Dorothea C. Leighton, M.D.

Associate Professor, Department of Anthropology, University of North Carolina; Clinical Associate Professor, Department of Psychiatry, North Carolina Memorial Hospital, Chapel Hill, North Carolina.

Paul V. Lemkau, M.D.

Professor and Chairman, Department of Mental Hygiene, School of Hygiene and Public Health, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Maurice Levine, M.D.

Professor and Director, Department of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio; Training Psychoanalyst, Chicago Institute for Psychoanalysis, Chicago, Illinois; Director, Psychiatry Service, Cincinnati General Hospital; Director, Central Psychiatric Clinic of the Community Chest, Cincinnati, Ohio.

Harold I. Lief, M.D.

Professor of Psychiatry, Tulane University School of Medicine; Director, Hutchinson Memorial Psychiatric Clinic, Tulane University School of Medicine; Senior Visiting Physician, Charity Hospital, New Orleans, Louisiana.

Victor F. Lief, M.D.

Associate Professor of Psychiatry, New York Medical College; Associate Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Associate Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Louis Linn, M.D.

Lecturer, Division of Community Psychiatry, Department of Psychiatry, Columbia University College of Physicians and Surgeons; Lecturer in Psychiatry, Mount Sinai Medical School, New York, New York.

Samuel Livingston, M.D.

Associate Professor of Pediatrics, Johns Hopkins University School of Medicine; Director and Physician-in-Charge, Epilepsy Clinic, Johns Hopkins Hospital, Baltimore, Maryland.

Sandor Lorand, M.D.

Professor of Clinical Psychiatry and Psychoanalytic Medicine, and Director, Division of Psychoanalytic Education, Department of Psychiatry, State University of New York Downstate Medical Center, Brooklyn, New York.

Reginald S. Lourie, M.D.

Professor of Pediatric Psychiatry, George Washington University School of Medicine; Director, Department of Psychiatry, Children's Hospital of the District of Columbia, and Hillcrest Children's Center, Washington, D. C.

Alfred O. Ludwig, M.D.

Clinical Associate in Psychiatry, Harvard Medical School; Director, Southard Clinic, Massachusetts Mental Health Center; Training Psychoanalyst and Faculty Member, Boston Psychoanalytic Institute, Boston, Massachusetts.

John E. Mack, M.D.

Clinical Associate in Psychiatry, Harvard Medical School; Associate Director of Psychiatry, Massachusetts Mental Health Center, Boston, Massachusetts.

Robert B. Malmo, Ph.D.

Professor of Psychology, Departments of Psychiatry and Psychology, McGill University School of Medicine; Director, Psychology Laboratory, Allan Memorial Institute of Psychiatry, Montreal, Quebec, Canada.

Arnold J. Mandell, M.D.

Associate Professor in Residence, Department of Psychiatry, University of California School of Medicine at Los Angeles; Director, Biochemical Correlates Laboratory, Neuropsychiatric Institute, University of California Medical Center; Associate Attending Physician, University of California at Los Angeles Health Science Center, Los Angeles, California.

James F. Masterson, Jr., M.D.

Associate Professor of Psychiatry, Cornell University Medical College; Associate Attending Psychiatrist, Payne Whitney Psychiatric Clinic, New York Hospital, New York, New York

David J. McClure, M.D., M.Sc., M.R.C.P.(I.)

Lecturer, Department of Psychiatry, McGill University School of Medicine; Assistant Psychiatrist, Royal Victoria Hospital, Montreal, Quebec, Canada.

Myer Mendelson, M.D.

Associate Professor of Psychiatry, University of Pennsylvania School of Medicine; Attending Psychiatrist, Institute of the Pennsylvania Hospital, Philadelphia, Pennsylvania.

Gerald M. Meredith, Ph.D.

Evaluation and Alumni Liaison Officer, Center for Cultural and Technical Interchange Between East and West, Honolulu, Hawaii.

Milton H. Miller, M.D.

Professor and Chairman, Department of Psychiatry, University of Wisconsin Medical School; Director, Wisconsin Psychiatric Institute, Madison, Wisconsin.

George Mora, M.D.

Assistant Clinical Professor of Psychiatry, New York Medical College; Lecturer, Department of Psychiatry, Columbia University College of Physicians and Surgeons, New York, New York; Research Associate, Department of History of Medicine, Yale University School of Medicine, New Haven, Connecticut; Medical Director, Astor Home for Children, Rhinebeck, New York.

Donald W. Mulder, M.D.

Professor of Neurology, Mayo Graduate School of Medicine, University of Minnesota School of Medicine;

Chairman, Department of Neurology, Mayo Clinic, Rochester, Minnesota.

Simon H. Nagler, M.D.

Clinical Professor of Psychiatry, New York Medical College; Associate Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Associate Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

John C. Nemiah, M.D.

Assistant Professor of Psychiatry and Tutor in Psychiatry, Harvard Medical School; Psychiatrist, Massachusetts General Hospital; Faculty, Boston Psychoanalytic Institute, Boston, Massachusetts.

Peter B. Neubauer, M.D.

Associate Clinical Professor of Psychiatry and Chairman, Child Psychoanalytic Section, Division of Psychoanalytic Education, State University of New York Downstate Medical Center; Visiting Psychiatrist, King's County Hospital, Brooklyn, New York; Director, Child Development Study Center, New York, New York.

William C. Normand, M.D.

Assistant Professor of Psychiatry, New York Medical College; Assistant Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Assistant Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Daniel Offer, M.D.

Associate Director, Institute for Psychosomatic and Psychiatric Research and Training, Michael Reese Hospital, Chicago, Illinois.

Helene Papanek, M.D.

Dean and Director, Alfred Adler Institute; Adjunct Psychiatrist, Lenox Hill Hospital; Faculty Member, Postgraduate Center for Mental Health; New York, New York; Adjunct Attending Psychiatrist, Hillside Hospital, Glen Oaks, New York; Consultant, Veterans Administration, Brooklyn, New York.

Lydia L. Pauli, M.D.

Assistant Professor of Pediatrics, Johns Hopkins University School of Medicine; Associate Director, Epilepsy Clinic, Johns Hopkins Hospital, Baltimore, Maryland.

Henry E. Payson, M.D.

Assistant Professor of Psychiatry, Dartmouth Medical School, Hanover, New Hampshire; Associate Psychiatrist, Veterans Administration Hospital, White River Junction, Vermont; Attending Psychiatrist, Mary Hitchcock Memorial Hospital, Hanover, New Hampshire.

Hildegard E. Peplau, R.N., Ed.D.

Professor and Director, Graduate Program in Psychiatric Nursing, Rutgers—The State University, College of Nursing, Newark, New Jersey.

Chester M. Pierce, M.D.

Associate Professor of Psychiatry, University of Oklahoma School of Medicine; Chief of Research in

Psychiatry, Veterans Administration Hospital, Oklahoma City, Oklahoma.

Zygmunt A. Piotrowski, Ph.D.

Professor of Psychology in Psychiatry and Head, Psychology Division, Department of Psychiatry, Jefferson Medical College of Philadelphia; Area Consultant in Psychology, Veterans Administration, Philadelphia, Pennsylvania.

Dane G. Prugh, M.D.

Professor of Psychiatry and Pediatrics, University of Colorado School of Medicine; Chief, Child Psychiatry Division, Department of Psychiatry, University of Colorado Medical Center, Denver, Colorado.

John D. Rainer, M.D.

Associate Clinical Professor of Psychiatry, Columbia University College of Physicians and Surgeons; Acting Chief of Psychiatric Research (Medical Genetics), New York State Psychiatric Institute, New York, New York.

David M. Reed, Ph.D.

Assistant Professor, Psychodynamics and Mental Hygiene, Department of Psychiatry and Neurology, Tulane University School of Medicine, New Orleans, Louisiana.

Morton F. Reiser, M.D.

Professor of Psychiatry, Albert Einstein College of Medicine of Yeshiva University; Chief, Division of Psychiatry, Montefiore Hospital and Medical Center, Bronx, New York.

Herbert S. Ripley, M.D.

Professor and Chairman, Department of Psychiatry, University of Washington School of Medicine; Psychiatrist-in-Chief, University Hospital; Consultant, Veterans Administration Hospital, Seattle, Washington.

Eli Robins, M.D.

Wallace Renard Professor of Psychiatry and Head, Department of Psychiatry, Washington University School of Medicine; Psychiatrist-in-Chief, Barnes and Renard Hospitals, St. Louis, Missouri.

J. Franklin Robinson, M.D. (deceased)

Late Director, Children's Service Center of Wyoming Valley; Late Senior Chief, Psychiatric Service, Wilkes-Barre General Hospital, Wilkes-Barre, Pennsylvania.

Carl R. Rogers, Ph.D.

Resident Fellow, Western Behavioral Sciences Institute, La Jolla, California.

Milton Rosenbaum, M.D.

Professor and Chairman, Department of Psychiatry, Albert Einstein College of Medicine of Yeshiva University; Director, Psychiatric Service, Bronx Municipal Hospital Center, Bronx, New York.

W. Donald Ross, M.D.

Professor of Psychiatry and Assistant Professor of Industrial Medicine, University of Cincinnati College of

Medicine; Attending Psychiatrist, and Clinician, Out-patient Department (Psychiatry and Medicine), and Director, Psychosomatic Service and Non-Psychiatrist Physician Special Training, Cincinnati General Hospital, Cincinnati, Ohio.

Jack L. Rubins, M.D.

Associate Clinical Professor of Psychiatry, New York Medical College; Associate Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Associate Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home; Lecturer, American Institute of Psychoanalysis, New York, New York.

Jurgen Ruesch, M.D.

Professor of Psychiatry, University of California School of Medicine at San Francisco; Director, Section of Social Psychiatry, Langley Porter Neuropsychiatric Institute, San Francisco, California.

Melvin Sabshin, M.D.

Professor and Head, Department of Psychiatry, University of Illinois College of Medicine; Attending Physician, Michael Reese Hospital; Consultant in Psychiatry, Presbyterian-St. Luke's Hospital, Chicago, Illinois.

Clifford J. Sager, M.D.

Professor of Psychiatry and Director, Partial Hospitalization Center, New York Medical College; Associate Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Visiting Psychiatrist, Metropolitan Hospital, New York, New York.

Leon Salzman, M.D.

Clinical Professor of Psychiatry, Georgetown University School of Medicine; Faculty, Washington School of Psychiatry; Visiting Lecturer, Catholic University Graduate School; Consultant, St. Elizabeth's Hospital, Washington, D. C.

William L. Sands, M.D.

Professor of Psychiatry and Director of Residency Training, Albany Medical College of Union University; Attending Psychiatrist, Albany Medical Center Hospital; Consultant in Psychiatry, Albany Veterans Administration Hospital, Albany, New York.

Lindbergh S. Sata, M.D.

Assistant Professor of Psychiatry, University of Maryland School of Medicine; Director, Division of Community Psychiatry, The Psychiatric Institute, Baltimore, Maryland.

Raul Schiavi, M.D.

Assistant Professor of Psychiatry, State University of New York Downstate Medical Center, Brooklyn, New York.

Henry I. Schneer, M.D.

Associate Professor of Psychiatry and Psychoanalytic Medicine, State University of New York Downstate Medical Center; Visiting Psychiatrist, Kings County Hospital, Brooklyn, New York.

Elvin V. Semrad, M.D.

Clinical Professor of Psychiatry, Harvard Medical School; Director of Psychiatry, Massachusetts Mental Health Center; Faculty, Boston Psychoanalytic Institute, Boston, Massachusetts.

Charles Shagass, M.D.

Professor of Psychiatry, Temple University School of Medicine; Senior Medical Scientist, Eastern Pennsylvania Psychiatric Institute, Philadelphia, Pennsylvania.

Robert L. Sharoff, M.D.

Associate Professor of Psychiatry, New York Medical College; Assistant Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Associate Visiting Psychiatrist, Bird S. Coler Memorial Hospital and Home; Associate Visiting Psychiatrist and Director of the Narcotics Service, Metropolitan Hospital, New York, New York.

Irving Silverman, Ph.D.

Assistant Professor of Psychiatry, Division of Community Mental Health, Department of Psychiatry, New York Medical College, New York, New York.

Charles J. Smith, Ph.D.

Associate Professor of Psychology, State University of New York at Buffalo, Buffalo, New York.

Philip Solomon, M.D.

Associate Clinical Professor of Psychiatry, Harvard Medical School; Physician-in-Chief, Psychiatry Service, Boston City Hospital, Boston, Massachusetts.

Seymour Solomon, M.D.

Assistant Professor of Clinical Neurology, Albert Einstein College of Medicine of Yeshiva University; Director of Electroencephalography Laboratory, and Attending Neurologist, Montefiore Hospital and Medical Center, Bronx-Lebanon Hospital Center, and Morrisania City Hospital, Bronx, New York.

Meyer Sonis, M.D.

Associate Professor of Psychiatry and Chief, Division of Child Psychiatry, University of Pittsburgh School of Medicine; Associate Professor of Child Psychiatry, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania.

Herbert Spiegel, M.D.

Assistant Clinical Professor of Psychiatry, Columbia University College of Physicians and Surgeons; Associate Attending Psychiatrist, St. Luke's Hospital; Assistant Attending Psychiatrist, Columbia-Presbyterian Medical Center, New York, New York.

Edward Stainbrook, M.D., Ph.D.

Professor and Chairman, Department of Psychiatry, University of Southern California School of Medicine; Chief Psychiatrist, Los Angeles County General Hospital, Los Angeles, California.

Marvin Stein, M.D.

Professor and Chairman, Department of Psychiatry, State University of New York Downstate Medical

Center; Director of Psychiatric Service, Kings County Hospital Center, Brooklyn, New York.

Robert L. Stewart, M.D.

Professor of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio; Lecturer and Research Associate, Chicago Institute for Psychoanalysis, Chicago, Illinois.

Robert L. Stubblefield, M.D.

Professor and Chairman, Department of Psychiatry, University of Texas Southwestern Medical School, Dallas, Texas.

Albert J. Stunkard, M.D.

Professor and Chairman, Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.

Joseph D. Teicher, M.D.

Professor of Psychiatry, University of Southern California School of Medicine; Director, Children's and Adolescents' Psychiatric Services, Los Angeles County General Hospital; Faculty, Southern California Psychoanalytic Institute, Los Angeles, California

James L. Titchener, M.D.

Associate Professor of Psychiatry, University of Cincinnati College of Medicine; Attending Psychiatrist, Cincinnati General Hospital, Cincinnati, Ohio.

Hugh Urban, Ph.D.

Associate Professor of Psychology, Pennsylvania State University; Coordinator, Psychotherapy Program, Division of Counseling, Pennsylvania State University, University Park, Pennsylvania.

Harold M. Visotsky, M.D.

Associate Professor of Psychiatry, University of Illinois College of Medicine; Director, Illinois Department of Mental Health; Attending Physician, Michael Reese Hospital; Attending Physician, Forest Hospital and St. Luke's-Presbyterian Hospital, Chicago, Illinois.

Raymond W. Waggoner, M.D., Sc.D.

Professor and Chairman, Department of Psychiatry, University of Michigan Medical School; Director, Neuropsychiatric Institute, University of Michigan Hospital, Ann Arbor, Michigan.

Anthony F. C. Wallace, Ph.D.

Professor and Chairman, Department of Anthropology, University of Pennsylvania; Professor of Anthropology in Department of Psychiatry, University of Pennsylvania School of Medicine; Senior Research Scientist, Eastern Pennsylvania Psychiatric Institute, Philadelphia, Pennsylvania.

Edith H. Weigert, M.D.

Chairman of Faculty, Washington School of Psychiatry; Training Psychoanalyst, Washington Psychoanalytic Institute, Washington, D. C.

Herbert Weiner, M.D.

Professor of Psychiatry, Albert Einstein College of Medicine of Yeshiva University; Associate Chief,

Division of Psychiatry, Montefiore Hospital and Medical Center, Bronx, New York.

Leonard Weinroth, M.D.

Associate Clinical Professor of Psychiatry, Mount Sinai Medical School; Associate Attending in Psychiatry, Mount Sinai Hospital, New York, New York.

Robert J. Weiss, M.D.

Professor and Chairman, Department of Psychiatry, Dartmouth Medical School; Chairman, Department of Psychiatry, Hitchcock Clinic; Staff, Mary Hitchcock Memorial Hospital, Hanover, New Hampshire.

Louis J. West, M.D.

Professor and Chairman, Department of Psychiatry, Neurology, and Behavioral Sciences, University of Oklahoma School of Medicine; Psychiatrist-in-Chief, University of Oklahoma Hospitals, Oklahoma City, Oklahoma.

Edward C. Whitmont, M.D.

Training Psychoanalyst, C. G. Jung Institute for Analytical Psychology of New York, New York, New York.

Abraham Wikler, M.D.

Professor of Psychiatry and Pharmacology, University of Kentucky College of Medicine; Attending Physician, University of Kentucky Hospital, Lexington, Kentucky.

Otto A. Will, Jr., M.D.

Clinical Professor of Psychiatry, University of Maryland School of Medicine, Baltimore, Maryland; Director of Psychotherapy, Chestnut Lodge, Rockville,

Maryland; Training Psychoanalyst, Washington Psychoanalytic Institute, Washington, D. C.

Ethel A. Wilson

Special Assistant to the General Director, Beth Israel Medical Center, New York, New York.

Eric D. Wittkower, M.D.

Professor of Psychiatry, and Director, Section of Transcultural Psychiatric Studies, Department of Psychiatry, McGill University School of Medicine; Consulting Psychiatrist, Royal Victoria Hospital, Montreal General Hospital, and Queen Elizabeth Hospital, Montreal, Quebec, Canada.

Alexander Wolf, M.D.

Associate Clinical Professor of Psychiatry, New York Medical College; Associate Attending Psychiatrist, Flower and Fifth Avenue Hospitals; Associate Visiting Psychiatrist, Metropolitan Hospital and Bird S. Coler Memorial Hospital and Home, New York, New York.

Henry H. Work, M.D.

Professor of Psychiatry and Head, Division of Child Psychiatry, University of California at Los Angeles School of Medicine, Los Angeles, California.

Leon J. Yarrow, Ph.D.

Chief, Personality Development Section, Behavioral Science Branch, National Institute of Child Health and Human Development, Bethesda, Maryland.

Stanley F. Yolles, M.D.

Director, National Institute of Mental Health, Bethesda, Maryland.

Preface	v
List of Contributors	ix

AREA A—HISTORY OF PSYCHIATRY...1

Chapter 1 History of Psychiatry	2	1.1 History of Psychiatry	2
		GEORGE MORA, M.D.	

AREA B—BASIC BEHAVIORAL SCIENCES...35

Chapter 2 Basic Biological Sciences.	37	3.4 Motivation	172
2.1 Genetics and Psychiatry	37	ROBERT B. MALMO, PH.D.	
JOHN D. RAINER, M.D.		3.5 Ethology	180
2.2 Neurochemistry		ECKHARD H. HESS, PH.D. . .	
WILLIAMINA A. HIMWICH, PH.D., AND		3.6 Social Communication	189
HAROLD E. HIMWICH, M.D.	49	JURGEN RUESCH, M.D.	
2.3 Psychopharmacology	67		
HAROLD E. HIMWICH, M.D.		Chapter 4 Basic Sociocultural Sciences	195
2.4 Sleep and Dreams	77	4.1 Anthropology and Psychiatry	195
WILLIAM C. DEMENT, M.D., PH.D.		ANTHONY F. C. WALLACE, PH.D.	
Neurophysiology and Neuroanatomy		✓ 4.2 Sociology and Psychiatry	201
2.5 The Neuron	89	IRVING SILVERMAN, PH.D.	
ROBERT W. DOTY, PH.D.		4.3 The Role of the Family in Psychiatry	213
2.6 The Nerve Impulse and Synaptic	97	STEPHEN FLECK, M.D.	
Transmission		Chapter 5 Other Fundamental Topics	225
ROBERT W. DOTY, PH.D.		5.1 Epidemiology	225
2.7 Electrical Activity of the Brain	112	PAUL V. LEMKAU, M.D., AND GUIDO M.	
ROBERT W. DOTY, PH.D., AND CHARLES		CROCETTI, B.SC.	
J. SMITH, PH.D.		5.2 Computers and Psychiatry	232
2.8 Limbic System	125	MAX FINK, M.D.	
ROBERT W. DOTY, PH.D.		Experimental Psychopathology	
2.9 Cerebral Cortex	143	✓ 5.3 Experimental Neurosis	238
CHARLES J. SMITH, PH.D.		CHARLES SHAGASS, M.D.	
Chart—Functions of the Cerebral Cortex	147	5.4 Hallucinogens	247
SEYMOUR SOLOMON, M.D.		ARNOLD J. MANDELL, M.D., AND LOUIS	
2.10 Neurophysiological Correlates of	149	J. WEST, M.D.	
Learning and Behavior		✓ 5.5 Sensory Deprivation	253
E. ROY JOHN, PH.D.		PHILIP SOLOMON, M.D.	
Chapter 3 Basic Psychological Sciences	152	Normality	
3.1 Perception	152	5.6 Concepts of Normality in Psychiatry	255
CYNTHIA P. DEUTSCH, PH.D.		DANIEL OFFER, M.D., AND MELVIN	
3.2 Cognition	158	SABSHIN, M.D.	
MARTIN DEUTSCH, PH.D.		✓ 5.7 Normal Psychosexual Functioning	258
3.3 Learning	166	HAROLD I. LIEF, M.D., AND DAVID M.	
ARTHUR J. BACHRACH, PH.D.		REED, PH.D.	

AREA C—CURRENT THEORIES OF PERSONALITY AND PSYCHOPATHOLOGY...267

Chapter 6 Classical Psychoanalysis..... 269

- 6.1 Classical Psychoanalysis
JOHN E. MACK, M.D., AND ELVIN V. SEMRAD, M.D..... 269

Chapter 7 Cultural and Interpersonal Psychoanalytic Theories..... 320

- 7.1 Alfred Adler HELENE PAPANEK, M.D. 320
7.2 Karen Horney JACK L. RUBINS, M.D.. 327
7.3 Harry Stack Sullivan
LEON SALZMAN, M.D..... 338
7.4 Erich Fromm
SIMON H. NAGLER, M.D. 351
7.5 Sandor Rado
HOWARD DAVIDMAN, M.D. 355

Chapter 8 Other Psychoanalytic and Psychodynamic Theories..... 363

- 8.1 Adolf Meyer GEORGE MORA, M.D.. 363

- 8.2 Carl Jung EDWARD WHITMONT, M.D. 366

- 8.3 Otto Rank SIMON H. NAGLER, M.D... 372

- 8.4 Melanie Klein
SIMON H. NAGLER, M.D. 376

- 8.5 Wilhelm Reich
SIMON H. NAGLER, M.D. 379

- 8.6 Jules Masserman
SIMON H. NAGLER, M.D. 381

- 8.7 Existential Psychoanalysis
EDITH WEIGERT, M.D. 383

Chapter 9 Personality Theories Derived from Psychology..... 388

- 9.1 Personality Theory Derived from Quantitative Experiment
RAYMOND B. CATTELL, PH.D., D.SC. 388

- 9.2 Other Psychological Personality Theories
RAYMOND B. CATTELL, PH.D., D.SC., AND GERALD M. MEREDITH, PH.D. 410

✓ AREA D—NEUROLOGY...419

Chapter 10 Neurology..... 420

- Introduction SEYMOUR SOLOMON, M.D..... 420

- ✓10.1 The Neurological Evaluation
SEYMOUR SOLOMON, M.D..... 420

- 10.2 Anatomy and Physiology of the Cen-

- tral Nervous System
SEYMOUR SOLOMON, M.D. 443

- 10.3 Clinical Neurology and Neuropathology SEYMOUR SOLOMON, M.D.. 447

- 10.4 Other Neurological Syndromes
SEYMOUR SOLOMON, M.D. 473

AREA E—ASSESSMENT IN PSYCHIATRY...487

Chapter 11 The Psychiatric Examination.. 491

- 11.1 Psychiatric Interview
HERBERT S. RIPLEY, M.D..... 491
11.2 Psychiatric History and Mental Status WILLIAM L. SANDS, M.D. 499

Chapter 12 Ancillary Data in Psychiatric Assessment..... 509

- ✓12.1 Psychological Testing of Intelligence and Personality
ZYGMENT A. PIOTROWSKI, PH.D..... 509
✓12.2 Psychological Tests for Brain Damage
ARTHUR L. BENTON, PH.D..... 530

Chart—Some Instruments Commonly Used by Clinical Psychologists

- HERBERT FENSTERHEIM, PH.D.... 539
12.3 Social Service Information
C. KNIGHT ALDRICH, M.D.... 541
12.4 The Medical Examination in Psychiatric Assessment VICTOR F. LIEF, M.D. 542

Chapter 13 Clinical Manifestations of Psychiatric Disorders..... 546

- ✓13.1 Clinical Manifestations of Psychiatric Disorders LOUIS LINN, M.D..... 546

AREA F—THE PSYCHIATRIC SYNDROMES...579

Chapter 14 Classification in Psychiatry.. 581

- ✓14.1 Nosology HENRY BRILL, M.D..... 581
✓14.2 Neurosis, Psychosis, and the Borderline States MILTON H. MILLER, M.D.. 589

Chapter 15 Psychotic Disorders. I: Schizophrenic Reactions..... 593

- 15.1 Schizophrenia. I: Introduction and History HEINZ E. LEHMANN, M.D.... 593

15.2	Schizophrenia. II: Epidemiology GUIDO M. CROCKETT, B.SC., AND PAUL V. LEMKAU, M.D.....	599	20.1	Brain Syndromes Associated with Trauma HENRY W. BROSIN, M.D.....	748
15.3	Schizophrenia. III: Etiology HERBERT WEINER, M.D.....	603	20.2	Brain Syndromes Associated with Drug or Poison Intoxication EBBE C. HOFF, M.D., PH.D.....	759
15.4	Schizophrenia. IV: Clinical Features HEINZ E. LEHMANN, M.D.....	621	20.3	Brain Syndromes Associated with Infection DONALD W. MULDER, M.D., AND ALLAN J. D. DALE, M.D.....	775
15.5	Schizophrenia. V: Psychological Treat- ment OTTO ALLEN WILL, JR., M.D.....	649	20.4	Brain Syndromes Associated with Intracranial Neoplasm RAYMOND W. WAGGONER, M.D., SC.D....	786
15.6	Schizophrenia. VI: Organic Therapy MAX FINK, M.D., AND TURAN M. ITIL, M.D.....	661	Chapter 21 Brain Disorders. IV: Associated with Convulsions (Epilepsy).....	795	
Chapter 16 Psychotic Disorders. II: Para- noid Reactions.....	665	21.1	Brain Disorders. IV: Associated with Convulsions (Epilepsy) FRANK R. ERVIN, M.D.....	795	
16.1	Paranoid Reactions NORMAN A. CAMERON, M.D., PH.D....	665	Chapter 22 Mental Retardation.....	817	
Chapter 17 Psychotic Disorders. III: Affec- tive Reactions.....	676	22.1	Mental Retardation LEON CYTRYN, M.D., AND REGINALD S. LOURIE, M.D.....	817	
17.1	Manic-Depressive Reactions ROBERT A. COHEN, M.D., PH.D.....	676	Chapter 23 Psychoneurotic Disorders. I: Anxiety, Conversion, Dissociative, and Phobic Reactions.....	857	
17.2	Psychotic Depressive Reaction PAUL E. HUSTON, M.D.....	688	23.1	Anxiety Reaction HAROLD I. LIEF, M.D.....	857
17.3	Involuntional Psychotic Reaction HAMILTON FORD, M.D.....	697	23.2	Conversion Reaction JOHN C. NEMIAH, M.D.....	870
<i>Chart—Some Psychological Test Characteris- tics of Depression</i> HAROLD A. GOOLISHIAN, PH.D.....	704	23.3	Dissociative Reaction LOUIS J. WEST, M.D.....	885	
Chapter 18 Brain Disorders. I: Introduction.....	706	23.4	Phobic Reaction SHERVERT H. FRAZIER, M.D., AND ARTHUR C. CARR, PH.D.....	899	
18.1	Introduction to Brain Disorders GEORGE L. ENGEL, M.D.....	706	Chapter 24 Psychoneurotic Disorders. II: Obsessive-Compulsive and Neurotic De- pressive Reactions.....	912	
18.2	Acute and Chronic Brain Syndromes HENRY W. BROSIN, M.D.....	708	24.1	Obsessive-Compulsive Reaction JOHN C. NEMIAH, M.D.....	912
18.3	Delirium GEORGE L. ENGEL, M.D.....	711	24.2	Neurotic Depressive Reaction MYER MENDELSON, M.D.....	928
Chapter 19 Brain Disorders. II: Associated with Disturbances in Circulation, Nu- trition, and Metabolism and with Un- known Causes.....	717	Chapter 25 Personality Disorders. I: Trait and Pattern Disturbances.....	937		
19.1	Brain Syndromes Associated with Circulatory Disturbances EWALD W. BUSSE, M.D., SC.D.....	717	25.1	Trait and Pattern Disturbances EUGENE B. BRODY, M.D., AND LINDBERGH S. SATA, M.D.....	937
19.2	Brain Syndromes Associated with Disturbances in Metabolism, Growth, and Nutrition EWALD W. BUSSE, M.D., SC.D.....	726	Chapter 26 Personality Disorders. II: Socio- pathic Type: Antisocial Disorders and Sexual Deviations.....	951	
19.3	Brain Syndromes Associated with Diseases of Unknown Cause RAYMOND W. WAGGONER, M.D.....	740	26.1	Antisocial and Dyssocial Personality Disorders ELI ROBINS, M.D.....	951
Chapter 20 Brain Disorders. III: Associated with Trauma, Poisons, Drugs, Infection, and Neoplasm.....	748				

Sexual Deviations

- 26.2 Sexual Deviations. I: Introduction
IRVING BIBER, M.D. 959
- 26.3 Sexual Deviations. II: Homosexuality
IRVING BIBER, M.D. 963
- 26.4 Sexual Deviations. III: Fetishism,
Transvestitism, Masochism, Sadism,
Exhibitionism, Voyeurism, Incest,
Pedophilia, and Bestiality
SANDOR LORAND, M.D., AND
HENRY I. SCHNEER, M.D. 977

Chapter 27 Personality Disorders. III:

- Sociopathic Type: The Addictions** 989
- 27.1 Addictions. I: Opioid Addiction
ABRAHAM WIKLER, M.D. 989
- 27.2 Addictions. II: Non-Narcotic Addic-
tive Agents JOHN A. EWING, M.D. . . . 1003
- 27.3 Addictions. III: Alcoholism
MORRIS E. CHAFETZ, M.D. 1011

**Chapter 28 Personality Disorders. IV: Gross
Stress Reaction** 1027

HISTORY OF PSYCHIATRY

Chapter 1

History of Psychiatry

1.1 • • •

GEORGE MORA, M.D.

The history of psychiatry has become an increasingly popular subject for many laymen. However, it is of particular importance to psychiatrists who recognize that knowledge of the historical developments in the field can enhance their understanding of current psychiatric concepts and practices. In recent years this interest in the history of psychiatry has led to historical sessions at national psychiatric conventions and commemorative exhibits at such meetings. Libraries include reprints of important works of the past and, most important of all, there has been a rapid growth of literature focusing on the historical evolution of psychiatry.

Nevertheless, the history of psychiatry remains a very difficult subject to deal with, and only a few publications of the many which have appeared in recent years have contributed substantially to our better understanding in this area. Traditionally, the history of psychiatry had been conceived of as a series of biographies of those men who had fought to free mental patients from their chains on the basis of their optimistic view of man's potentialities, and, in the late 18th century, their belief in the perfectibility of man and in the progress of society. During the second half of the 19th century, this benevolent attitude toward mental patients arose from the conviction that psychic phenomena did not stem from supernatural forces, but were the result of physiological factors. Specifically, those presentations of German derivation emphasized these trends to account for future developments.

In retrospect, it was inevitable that in due time increasing acceptance of psychoanalysis, leading to the psychodynamic orientation currently predominant in psychiatry, should have eventually brought about a focus on historical and developmental matters, since psychoanalysis is concerned with the genetic-historic study of personality. Freud and his early pupils, however, were so engrossed in establishing a clinical basis

for their new science that they overlooked its historical foundations. Furthermore, like any new intellectual movement, a sufficient time had to elapse before psychoanalysis could be viewed in historical perspective. Gregory Zilboorg's *A History of Medical Psychology*, which appeared 25 years ago as the first modern work on this subject, is still considered by many to be the finest presentation of the development of psychiatry from the psychoanalytic viewpoint. That is, Zilboorg's volume emphasized the role and contribution of those scientists who anticipated the evolution of psychoanalytic concepts.

A few years earlier, in 1937, a book by Albert Deutsch, a layman, entitled *The Mentally Ill in America*, which soon became a classic, had appeared. Here, unlike its historical, scientific antecedents, Deutsch emphasized current social, cultural, and religious factors which created conditions favorable, or unfavorable, to psychiatric progress. The description of these factors permitted a better understanding of personality and of its aberrations and, more concretely permitted elaboration of more effective treatment methods for ambulatory as well as hospitalized mental patients.

In a broad sense, this polarity in emphasis on individual personality development versus the mental health of a society may be compared to the polarity of neurosis versus psychosis. The treatment of the neurosis is based primarily on psychodynamic understanding of the "unconscious," which is the repository of the individual's psychological experiences throughout his life time. On the other hand, treatment of psychosis, while it may involve specific techniques, will depend above all on the dedicated understanding and the care-taking facilities provided by an enlightened society. Thus the history of psychiatry can be presented from either of these orientations in much the same way as history in general: one may emphasize the personalities who, breaking with tradition, came to shape the scientific future, or the social events which favored the emergence of such personalities.

Regardless of how basic this antithesis remains in any historical presentation, including psychiatry, modern historiography is attempting to bridge the

gap between these two essential categories. As far as the history of psychiatry is concerned, the moment now seems ripe for the integration of these areas of emphasis—the individual personalities which shaped the progress of psychiatry and the complex social and cultural background which made possible such progress. The components of this background include religious beliefs and rituals (expressions of collective psychopathology) and literary and figurative productions, which must be understood particularly in relation to advances in anthropology, ethnology, and the history of religions, as well as advances in other behavioral sciences.

The presentation of the history of psychiatry which follows has been chronologically assembled. It should be pointed out that these chronological divisions do not denote definite interruptions or changes in the stream of events; rather, they represent didactic landmarks which are designed to facilitate the comprehension of the subject matter.

Finally, it was possible to withstand the temptation to emphasize only those events which anticipated current psychiatric concepts and to disregard those events which we now know have not added significantly to our present psychiatric knowledge. Thus, every effort was made to avoid a clear cut antinomy of “discoveries” and “errors,” an attitude that in the history of science is labeled “presentism” or “inductivism.” Rather, an effort has been made to present these events within the framework of a “continuity theory,” according to which scientific progress develops on the basis of the indebtedness of all contributors to their predecessors, the truth finally emerging from this scientific continuity. This is not easy to achieve; since psychodynamic thinking is prevalent in psychiatry, the pendulum tends to swing only toward events of the past which have anticipated this psychodynamic orientation. Because this is a general textbook of psychiatry, however, and not a textbook on psychodynamics, events which anticipated modern methods of physical psychiatric therapy, psychopharmacology, hospital care, etc., as well as those which led to the psychodynamic focus, have been given due recognition.

In brief, each reader will be able to identify the historical antecedents of his own philosophy of psychiatry.

Psychiatry in Primitive Cultures

Methodological considerations. In the last 2 decades, coinciding with the achievement of independence and the progressive “acculturation” of many Afro-Asian countries, the status of mental health and conversely of mental disease of many ethnic groups has been the focus of increasing attention. In the past, ethnologists, such as Taylor, Morgan, and Frazer, in describing the mores of primitive cultures, tended to stress their peculiarities and differences in relation to Western culture. In contrast, today anthropologists are making a greater effort to understand psychologi-

cal manifestations of primitive cultures in the context of a general theory of human behavior. Since the term “primitive cultures” is somewhat vague and has been used interchangeably to refer to ethnic groups of the past as well as to some underdeveloped areas of the present, Ackerknecht’s suggestion to use the term “paleo medicine” to refer to ancient man and “primitive medicine” to refer to contemporary tribes appears to have merit. Thus, “paleo psychiatry” may be differentiated from “primitive” or “folk psychiatry.”

Origins of mental illness. There is ample evidence that concepts of the etiology of physical and mental disorders, both in “paleo” and in “primitive” medicine, were influenced by the universal belief in supernatural phenomena, specifically the influence of spirits of the ancestors of the clan. For example, trepanation of skulls, remnants of which were found in Peru, in probable cases of epilepsy or other violent behavioral expressions could be understood as an attempt to liberate the afflicted patient from the evil spirits in his head. Aside from the use of amulets, talismans, etc., which reflect the belief in the influence of spirits, there are no other remnants directly related to mental and nervous conditions in paleopathology. Further evidence must be gathered through study of the current practices of primitive cultures.

However, the study of contemporary primitive cultures poses two difficult methodological problems. First, Western researchers have been unable to modify substantially their “*forma mentis*,” with a consequent tendency toward naïveté and ethnocentrism in investigating other cultures. Secondly, most primitive cultures have undergone a process of acculturation with a consequent stratification of Western mores by indigenous ethnic groups. In order to overcome these difficulties, at least in part, a differentiation was introduced recently between: (1) autonormal and autopathological as applied to individuals regarded as normal or pathological, respectively, by their own society; and (2) heteronormal and heteropathological as applied to individuals regarded as normal or pathological, respectively, by members of another society observing them. As a result, the concept of normality as applied to primitive cultures has become a much more flexible and relative one, leaving room for a variety of manifestations which would be considered pathological according to the standards of Western culture. When it is considered in this light, the magical-religious system which influences the philosophy of primitive healing methods may be seen as an attempt to introduce rationality, and to meet socially expected needs in the apparently chaotic psychological experience of primitive man. Mental diseases represented a breakdown of the magical-religious system and were mainly attributed to violation of the taboo, neglect of ritual obligations, and demonic possessions.

Treatment of mental illness. In the study of the treatment of mental diseases in primitive man, the

4 History of Psychiatry

person encountered most frequently was the shaman (a word derived from the Tungus language of Northern Siberia). The shaman emerges as an inspirational type of medicine man, who was most vulnerable to possession by spirits, and through whom the spirits spoke. Early anthropological reports emphasized the dramatic aspects of the shaman's performance, that is, the actual appearance of the spirits in the course of highly emotionally charged séances. However, more recent studies emphasize the leading social role of the shaman, as well as his psychotherapeutic function. Typically, the shamanic séance took place in the presence of a selected group of participants. It involved a progressively increasing state of excitement on the part of the shaman, which was induced by heavy smoking, drinking, and drugs accompanied by rhythmic music (especially drums), to the point of paroxysm, characterized by partial loss of consciousness and unusual movements. The shaman revealed the presence of the spirits through utterances and violent actions. The mentally disturbed patients, in the course of active participation in the ceremony, might confess their sins or ask for the removal of certain disturbances specifically attributed to an evil spirit. The excursion of the shaman into the realm of the spirits was symbolic of the restoration of the patient's peace of mind (through sacrifices and other symbolic means). Frequently the liberation of the evil causes of disturbance from the body of the patient was expressed concretely through the actual expulsion of an object (stone, insect, hair) from the mouth of the shaman.

The personality of both the shaman and the mental patient treated by him have been the focus of much controversy. The opinion most commonly held is that the shaman was not psychotic or epileptic as originally believed but was essentially neurotic. As such, he might find an outlet for his own emotional instability through the séance, which represented almost an unconscious attempt at self-healing. Eligibility for the role of shaman required a particular state of receptivity to dreams and other psychological phenomena, elicited with the help of drugs and medicinal plants, and required a period of novitiate in isolation from the community. With regard to the patient who asked for the shaman's help, though difficult to translate into current psychiatric terminology, his symptoms appeared to range widely, from depression to withdrawal, and, for the most part, to be acute.

Shamanistic versus modern psychotherapeutic techniques. On the basis of these data, a comparison between shamanistic and modern psychotherapeutic procedures can be advanced. In both cases, the candidates for the role of healer have to undergo a period of relative seclusion from the community. While this carries a literal interpretation with regard to the shaman, it is comparable to the period of intensive study implied in all psychotherapeutic training, and particularly in psychoanalysis. Similarly, in both

cases, the acquisition of healing powers was facilitated by the interpretation of the dreams of the potential healer and other unconscious life events in the highly ambivalent context of the candidate-teacher relationship. Further, the healing process undergone by the patient could only be effective in an atmosphere of high social expectation in which roles and rituals were rigidly established and had the intrinsic purpose of guarding society from inner disintegrating forces. Concomitantly, recent studies have served to underscore the social aspect of the role of the shaman, i.e., to exploit and channel existing neurotic leanings in the community and relieve mental stress, in addition to his psychotherapeutic role in the treatment of individual patients.

Psychiatry at the Dawn of Civilization

Our present civilization had its beginnings in various areas of the Middle East at different times during the first two thousand years B.C. The remnants of these early civilizations have made it possible for researchers to reconstruct the high level of knowledge which was achieved in many fields of science; however, there is much less certainty about concepts of mental health and disease during this period because psychological concepts are closely interwoven with religious concepts, making their study and differentiation difficult. In spite of this, there is evidence of early attempts to describe mental phenomena, albeit in less concrete terms than those employed in primitive cultures.

The nature of existence. In Egyptian culture, life was viewed as a balance between man's static experience and his relationship to the universe, that is, an interaction between internal and external forces. This balance gave rise to rhythmic and cyclic happenings from birth to death, probably related to the cyclic result of the harvest caused by the Nile. The total personality was the result of seven forces, and included emotional, intellectual, and creative components. Emphasis on the supernatural, and especially communication with the dead, e.g., the spirits of the Pharaohs, was possible through a healing sleep induced by incubation techniques. (Of particular historical significance is Joseph's interpretation of the Pharaoh's dream of the seven fat and of the seven lean cows, reported in detail in the *Genesis*.) It is likely that treatment of mental disorders involved the integration of physical, psychic, and spiritual factors; this was accomplished through identification with positive constructive forces.

Interpretation of dreams. Of the various techniques possibly used to approach and modify personality, no other method in antiquity is more outstanding than the interpretation of dreams. According to the well documented study by Oppenheim on the Assyrian books of dreams, three types of dream experiences can be differentiated: (1) dreams which served as a vehicle for the revelation of a deity, and

which might or might not require interpretation; (2) dreams reflecting the state of mind of the dreamer, which were implied, but never recorded; and (3) dreams which foretold future events.

The message dream. Included in the first category is the "message dream," which appeared within a conventional "frame." Characteristically, the circumstances of the dream were reported with emphasis on the shocking experience undergone by the dreamer in the presence of the "deity" (who was usually represented as standing near his head and giving him a message). These reports then emphasized his surprise at awakening and, finally, mention is made of the fulfillment of the prediction or promise revealed in the dream. The message was expressed clearly (as in the Old Testament), or presented symbolically, in which cases the dreamer would require the services of an interpreter capable of "decoding" it. This decoding had to be accomplished as quickly as possible, so that the dreamer might not suffer unnecessarily from the "enigma" of the dream. Thus, the decoding of dreams served much the same purpose as the analysis of dreams does today. The difference lies in the fact that during this period dreams were always considered to refer to the future. In contrast, psychoanalysis has clearly established that dreams refer to the patient's past experiences.

Subjective dreams. The subjective state of mind of the dreamer, as reflected by the impact of physiological functions, such as sex, thirst, hunger (or indigestion), on the dream experience, is seldom mentioned, for fear that a description of the content of unpleasant dreams would make the evil things they portray come true.

Prophetic (or "mantic") dreams. The belief that the excursion of the sleeper into the nether world could reveal the future, which originated with the Greeks, is, once again, directly opposed to the psychoanalytic interpretation of dreams as related to individual past experiences. Yet, this belief in the prophetic function of the dream persists even today. In antiquity, dream content might be understood directly by the subject or he might require the help of dream interpreters. (The Egyptians were considered particularly skillful in this area, for example.) Of particular interest in this context is the fact that the later literature (especially Artemidorus Daldianus) did not concern itself with the philosophical implications of prognostics (in relation to individual religious and moral responsibility). Rather, it was concerned essentially with the collection of "dream-omina"; that is, dream content was classified and interpreted in a stereotyped way, very much in the same vein as today books on the interpretation of dreams which form part of the popular "literature."

Mental Illness in the Bible

In one of the oldest books of the Bible (*Deuteronomy*) it is said that God will punish those who violate

his commands with "madness, and blindness, and astonishment of heart," that is to say with mania, dementia and stupor.

Perhaps the most famous episode of insanity in the Bible refers to the case of Saul, who, following some disturbed behavior early in life, developed abnormal irritability, great suspiciousness and uncontrollable impulses which ended in suicide; apparently his was a case of manic-depressive psychosis.

Also worth remembering is the case of Nebuchadnezzar, King of Babylon, who became very depressed, irritable, uncontrollable, and finally fell into a condition called "lycanthropy" (a form of mental disorder in which the patient imagines himself to be a wolf or other wild beast, reported in the literature until the 17th century), which is probably a form of melancholia.

Later on, in the Jewish *Talmud*, insanity and epilepsy were considered as definite diseases, rather than supernatural phenomena, to be treated by the doctor and not by the priest; strangely enough, however, treatment consisted not of drugs, but of charms.

Psychiatry in Greek and Roman Culture

During the second part of the 19th century, as a concomitant of the philological and archeological investigations of the Greek world, several studies, among which Rhode's is particularly prominent, touched upon psychological and psychiatric concepts. The initial interest engendered by these studies gradually declined. Recently, however, it has been revived by modern psychodynamic theories which follow Jung's and Rank's early applications of mythological concepts to human behavior. The studies of Snell, Onians, and Jaeger and, more recently, the work of Dodds are particularly significant in this connection.

The Greek concept of "madness." Essentially, the description of "madness" in Greek culture derives from three main sources: popular opinion, medical knowledge, and literary-philosophical works. Each of these viewpoints prevailed at certain times and in turn, inevitably, they influenced each other. Consequently, a systematic presentation is almost impossible.

The popular conception. The popular concept of "madness" which was evident in primitive times (as represented in the vase paintings of that period) persisted throughout the development of the Greek culture, and, in fact, acquired further impetus during the Hellenistic era. Characteristic of the popular view was the belief in the supernatural causation of mental disorders. More specifically, individuals who were so afflicted were believed to be possessed by evil spirits (personified by the dread goddesses Mania and Lyssa), who had been sent by the gods in a state of anger. A particularly violent attack indicated more direct participation by the gods. At the same time, however, there is some indication that those individuals who manifested behavioral aberrations, and

were therefore believed to be possessed by evil spirits, may also have been regarded as sacred, as was the case in primitive cultures. Presumably, this was based on an unconscious fear of death, for the spirits represented the cult of the dead, and their persisting influence on the living.

As might be expected, this "popular" view provided no facilities for the treatment of the mentally ill. Milder cases were simply left to fare for themselves as objects of contempt, ridicule, and abuse. Those who were considered violent were kept at home, often in chains, on the assumption that the same gods who made people mad could cure them of it (in line with the homeopathic trend of Greek medical thinking). With regard to therapeutic techniques, in addition to the various cures by purification and participation in the mysteries, especially those of the Corybantes, a number of animal and vegetable substances were considered specific for the treatment of "madness" and epilepsy. Finally, no clear legal status was outlined for the mentally ill individual. Since his antisocial behavior was viewed as punishment by the gods (administered either directly or by their emissaries), the mentally ill criminal was relieved of any legal responsibility for his actions. Rather, the person convicted of a crime by reason of insanity was, as suggested by Plato, exiled from his city voluntarily, or forced to flee and to undergo purification rites. There was no psychiatric examination, except in cases involving slaves; in controversial cases, e.g., marriage, divorce, or adoption, appeal on psychiatric grounds was made to the "guardians of the law," rather than to physicians.

The medical conception. The medical concept of "madness," as elaborated in the Hippocratic writings (4th century B.C.), centered around the interaction of the four bodily humours (blood, black bile, yellow bile, and phlegm) which resulted from the combination of the four basic qualities in nature (heat, cold, moisture, and dryness). Individuals were classified according to four corresponding temperaments—sanguine, choleric, melancholic, or phlegmatic—which classification was considered to indicate their prevailing emotional orientation. Personality functioning reached an optimum level when "crasis," that is, the appropriate interaction of internal and external forces, had been achieved. Conversely, conflict between these forces, termed "discrasia," indicated the presence of excessive bodily humour, which had to be removed by purging.

Of greater significance, however, were the initial indications of a radical change in the concept of "madness," in the sense of diseases of the nervous system, which began to emerge at this time. This was first expressed by Hippocrates (460–355 B.C.) in the introduction to his treatise on epilepsy, *The Sacred Disease*. Even after many centuries, the viewpoint elaborated therein has not lost its philosophical value: "I do not believe that the 'sacred disease' is any

more divine or sacred than any other disease but, on the contrary, has specific characteristics and a definite cause. Nevertheless, because it is completely different from other diseases, it has been regarded as a divine visitation by those who, being only human, view it with ignorance and astonishment."

In Hippocrates' classic work other clinical pictures, apart from epilepsy, are today recognizable, namely, cases of psychoses (i.e., delusions due to distortions in sensory perceptions); impulse behavior disorders; melancholia; and, possibly, phobias. However, in the light of modern diagnostic criteria, these distinctions appear superficial and uncritical. All too frequently, "case histories" were restricted to the patient's own account of the onset of his illness and referred to etiological factors relating to malfunctioning of the brain or heart. In addition, as mentioned earlier, "madness" was commonly attributed to disturbance in the interaction of the four bodily humours, and an excess of black bile was mentioned with particular frequency as the cause of mental illness. Typically, the treatment in such cases involved the administration of a purgative, specifically, black hellebore. Thus, the line "Go to Anticyra," which appears in Aristophanes' (448–385 B.C.) *Vespae*, can be interpreted as a colloquialism that meant, "You are crazy," for Anticyra was famous as a source of hellebore. The treatment prescribed in such cases also included vapor, baths, and appropriate diet.

The literary-philosophical concept. The systematic study of Greek literary and philosophical works has resulted in a deeper and more meaningful approach to Greek psychological concepts at various stages in their development. In the time of Homer (10th–9th century B.C.), no definition of personality was advanced which might be equated with current concepts of personality. The three somewhat differentiated components of the soul—"psyche," "noos," and "thymos"—corresponded to the "organs" of life, rather than to psychological "functions," for action (i.e., thinking) had not yet been separated from its physical substrata (i.e., the brain). Thus, "psyche" (Greek *psyche*, to breathe) was conceptualized as the "breath of life," the force which kept the human being alive. Moreover, it persisted after life as the spirit of the dead, so that it might continue to influence one's living descendants.

The concept of the soul was divorced from the qualities of the body and its physical organs for the first time by Heraclitus (540–475 B.C.): "You could not find the ends of the soul though you traveled everywhere, so deep is its 'logos.'" Nevertheless, the awareness of psychological factors was acquired only very gradually. In the *Iliad*, human beings lacked personal motivation; instead, they were possessed by sudden feelings of power, almost comparable to states of temporary insanity. These feelings of power were believed to originate in the "thymos" or "phrenes," and were attributed to the gods, to *moira* (destiny), or to the

Section 1.1

Erinyes (i.e., goddesses of vengeance). In the *Odyssey*, there were implications of moral criticism, however; and, in time, the concept of *hybris* (arrogance) became prominent in terms of its link with success, complacency, sin, and guilt. In other words, the literary and philosophical works of the period began to evidence an awareness of the fact that moral principles (i.e., conscience) were internalized. They further stressed the relationship between the violation of these principles and consequent punishment by the gods as an inevitable part of man's destiny (*moira*). Such punishment might be inflicted in this life, in the other life, (i.e., after death), or even on one's descendants. Thus, in Plato, the "daemon" is no longer conceived of as an impersonal being; he has become a type of superego, which gave rise to a universal fear of gods and of pollution (*miasma*) and a craving for ritual purification (*catharsis*).

Stages in the development of Greek psychiatry.

In a broad sense, the transitional stages in the development of Greek psychiatry, as reflected in literary and philosophical writings, might be typified by the evolution of the concept of dreams. Initially, dreams were conceived of as part of reality. Subsequently, the dream was thought to be the creation of the gods, who used it as a mode of communicating with the dreamer. Finally, the dream was recognized as the product of the dreamer, and it was further recognized that the events portrayed therein might be interpreted in the light of their symbolic meaning (in the manner outlined by Hippocrates in *On Regimen*).

Yet, even within this framework, it is difficult to translate the psychological vocabulary of 5th century (B.C.) Greece, into modern terms. In general, however, developments during this period may be summarized as follows. Dreams were considered to perform a therapeutic function, in that originally they served to liberate the individual from adverse external forces and later on, from the impediment of his own body ("orphyic" tradition). Thus, the highly emotional group rites in praise of Dionysius, Greek god of fruitfulness and vegetation (especially wine), came to be replaced by mystic individualistic expressions, as typified by the puritanic community established by Pythagoras (6th century B.C.), which emphasized vegetarianism and purification by ritual means. Typically, such rituals included "recollection," to the degree that, in time, catharsis was considered the only means of salvation. Clearly, these practices might serve as a substitute for religious ritual. However, the 5th century also produced an agglomeration of religious beliefs. Thus, on the one hand, passion and immorality were conceived of as an expression of natural law (*physis*), and, on the other, as a conglomeration of irrational customs (*nomos*). While Protagoras (481-411 B.C.) believed that virtue must be acquired, like a habit, Socrates (470-399 B.C.) maintained that it had to be taught intellectually.

In any event, the fact remains that there was

greater acceptance of emotional manifestations of personality. This was particularly evident in dramatic productions: for the first time in *Ajax*, Sophocles' (495-406 B.C.) madman lived in an unreal, rather than a supernatural, world. Euripides' (ca. 484-407 B.C.) plays demonstrated what might almost be described as an esthetic appreciation of behavioral expressions of madness, such as hallucinations, and these were deliberately exaggerated in several of his plays (e.g., *Orestes*, *Heracles*, and *Pentheus*) for dramatic effect.

Plato's concept of madness. In *Phaedrus*, Plato (428-348 B.C.) described four kinds of madness: prophetic, telestic or ritual, poetic, and erotic. Prophetic madness was defined as a unique form of temporary insanity reserved for the few individuals who were able to reach the paroxysm of enthusiasm characteristic of the shamanistic trance, as typified by the ecstatic prophecy of Apollo's oracle at Delphi, and as immortalized in Aeschylus' (525-456 B.C.) *Cassandra*. Telestic or ritual madness typically signified freedom from instinctual needs achieved collectively during the Corybantic religious rites. These rites were characterized by orgiastic dances performed to music, especially flute and drum in Phrygian mode, accelerated to the point of paroxysm, and served a cathartic function. According to Plato's *Laws*, essentially, the Corybantic rites and the practice of rocking babies were based on the same therapeutic principle: "They restore the sufferers to a state of inner calm and repose and bring them back to their sober senses. Thus, the inner tumult is cured by outer activity; unwholesome mania is driven out by beneficent mania, and in the end both kinds of mania are gone." Poetic madness, due to possession by the muses, was described as a state of particular inspiration, which was bestowed by the gods on the artist in order to facilitate the process of creation. Finally, erotic madness was associated with human love, which in the Greek culture, included homosexual, as well as heterosexual relationships.

Therapeutic procedures: The phenomenon of incubation. Students of Plato have repeatedly pointed out the constant fluctuation of his philosophical emphasis between mysticism and rationalism. Perhaps this ambivalence can best be understood as a reflection of the political and social climate of his time, which had produced the enlightenment of Socrates and Euripides, as opposed to the superstitious wave which followed the disastrous Peloponnesian wars. It is in this light that the real meaning and importance in Greek culture of incubation, a method for the interpretation of dreams, should be evaluated.

In essence this phenomenon derives from the belief in the omnipotence of the souls of one's ancestors, and the concomitant homeopathic postulate that the same gods who inflicted diseases could also cure them. The god Asklepios played a central role in this phenomenon. Originally a daemon of Thessalian origin, Ask-

FIGURE 1. Asklepion of Epidaurus in its present status. The labyrinthine structure of the *tholos*, where mental patients had to walk and to sleep in order to be able to reach the center. In the course of this highly symbolic process, they were "healed" by the god while dreaming. From Kerenyi, C. *Antiquities of Asklepios: Images of the Phoenix and Existence* (English translation), p. 44. Pantheon Books, New York, 1959. lepios had undergone an interesting metamorphosis, from a mortal god in Homer to an underworld oracle-demon, and then to an Apollonian god, whose healing role was similar in certain respects to that of Christ. Of the many Greek temples dedicated to Asklepios ("Asklepieia") as settings for his divine manifestation (*epiphanias*), perhaps the most famous today is situated in Epidaurus, in the Peloponnesus (Figure 1).

Typically, the phenomenon of incubation, as described by Pausanias in the second century A.D., consisted of several stages: (1) Postulants, who were afflicted with a variety of physical and psychic diseases, were first subjected to ritual purification. (2) They then went to sleep in the *abaton* of the temple, namely, in underground corridors constructed to form a maze (Latin, *incubare*, to sleep in the holy room). While the patient slept, Asklepios would appear in his dreams as a man or child, or as a snake or dog; he would then "touch" the sick part of each patient's body, after which he would disappear. (3) The patient would wake up healed and would have his dream "decoded" by an interpreter. (4) Finally, the patient's dream (and his subsequent recovery) were regarded as a reward for his devotion to the god Asklepios, to whom he would then make further votive offerings (as in Plato's *Phaedo*).

Recently, Jungian psychiatrist C. A. Meier elaborated a thorough interpretation of the phenomenon of incubation in the light of modern dynamic psychiatry, emphasizing the symbolism of various aspects of the ritual. The spring connected with the place of altar or of sacrifice (*tholos*) was seen to have a therapeutic

significance. The purifying process undergone by the postulant and his unusual experience underground were equated with disintegration and reintegration. The fact that this experience (i.e., the dream) occurred during an altered state of consciousness under the effect of music in the darkness of the night might be compared to the ego regression which is a prerequisite for free association. Finally, just as psychoanalytic theory postulates that the goal of treatment is to make the patient conscious of the unconscious, the phenomenon of incubation equated cure with the patient's acceptance and understanding of the unconscious meaning of his disease.

Aristotle's empirical psychology. Plato made an impressive effort to explain irrational events and behavior as an inevitable part of human life, rather than as the result of noxious influences. And, concurrently, he attempted to subject them to the rational control of the mind. In contrast, Aristotle (384–322 B.C.) approached the various expressions of human behavior from an empirical viewpoint, which is more in keeping with today's psychology. Croissant's thorough presentation of Aristotle's explanation of the mysteries clearly establishes that he conceived of the mysteries as ritual happenings in the course of which mental disorder could be healed. Essentially, in accordance with the basic orphic theme, which Plato ascribed to as well, Aristotle believed that the disordered movement of the mysteries was ultimately conducive to order. Nor did he deviate substantially from general belief in his identification of the three irrational elements presented in these rituals: enthusiasm (i.e., a

state of temporary madness, related to sexuality); divination through dreams; and divination through chance. However, whereas according to the classical Pythagoric tradition the music which accompanied such rituals was considered to evoke harmony, Aristotle postulated that its therapeutic function was to arouse passions. This, then, was the first clear statement that the release of repressed emotions, or passions (i.e., abreaction), was an essential prerequisite for the effective treatment of mental illness, a viewpoint which was to serve as the basis for the so-called "moral treatment" in the early 19th century.

To this end, Aristotle further advocated the use of catharsis, wine, aphrodisiacs, and music as, in the final analysis, they all were found to produce similar effects, especially in people with melancholic constitutions. In summary, Aristotle discussed catharsis from a naturalistic viewpoint. More specifically, in contrast with Plato, he did not emphasize the occult and supernatural character of catharsis; rather he conceived of it as a natural outlet for disturbing passions. In fact, passions must be purged consistently to avoid violence. The use of the theater as a civic and collective cathartic device in Greek culture may be attributed largely to the wide acceptance of this belief.

The triumph of rationalism. Aristotle's empirical psychology did not undergo further development by his disciples. Instead, *ataraxia*, a mental state of imperturbability, became the ideal of the Epicureans and Stoics during the 3rd century B.C., and, concomitantly, the foundation of psychology became much more rationalistic. Recently, in this connection, Werner Leibbrand pointed out that the basic Stoic concept of *apatheia*, which emphasized the moderation of passions in every human act, played an eminent role throughout the development of psychopathology up to the present. In the 4th century B.C., the "conglomerate," the term used by Dodds to express the combination of rational and irrational motives in Platonic philosophy, broke down. With the rise of Hellenism, religion became more rationalistic in the following centuries. At the same time, astrology, neo-Pythagorism, and other irrational beliefs gained momentum. In general, there was a preoccupation with those beliefs which applied to individual salvation, and this preoccupation anticipated some of the major tenets of Christianity.

This description of the development of psychiatry in Greek culture might be appropriately concluded by a brief description of concurrent developments in other medical disciplines. At this point in our chronological account various schools of medical thought had begun to emerge and to acquire the distinct characteristics which were later to become well known in medical history: dogmatic, empirical, methodical, pneumatic, and eclectic. Alexandria became the new center of learning, and it was there, in the 3rd century B.C., that Erasistratus and Herophilus first described cor-

rectly parts of the nervous system, such as the ventricles, the sensory and motor nerves, the circumvolutions, the vessels at the base of the brain, the arachnoid and the dura mater.

The Roman concept of madness. In the succeeding 2 centuries, Rome acquired increasing political importance, but Greek culture continued to dominate those aspects of Roman life which related to philosophy and art. On the other hand, the Romans were particularly concerned with the practical aspects of existence, such as architecture, economics, and jurisprudence. With specific reference to psychiatry, for the most part, with minor variations, the popular and medical concepts of madness, as well as literary and philosophical writings, repeated the Greek themes, outlined above.

Popular concepts. Superstitious practices, influenced by autochthonous Etruscan beliefs, continued to determine the popular attitude toward the mentally ill, who were neglected, banned, or persecuted. Thus, according to the *Twelve Tables* (451-450 B.C.), the mentally ill were deprived of freedom of action and were judged incompetent to control their own personal and business affairs. On the stage, the Romans portrayed madness in the form of bacchantes, in which women carried snakes, wore bizarre costumes, and performed in frenzied ecstasy. In the *Aeneid*, Vergil (70-19 B.C.) conceived of madness to represent this same bacchic frenzy. Later, the Fury was used to imply an even more dramatic picture of madness, and in his *Metamorphoses*, Ovid (43 B.C.-17 A.D.) used not only the Fury, but hell broth, magic philters, and love potions, thus anticipating the paraphernalia typical of the medieval traditions and folk beliefs. Incubation practices became more frequent in Rome at the beginning of the 3rd century A.D., when an Asclepean temple was built on the Tiberine Island where the Fatebenefratelli Hospital now stands.

Medical concepts. Roman physicians continued to believe in the premonitory value of dreams, and, in general, to be influenced by Greek concepts; and this influence became particularly evident after Julius Caesar issued an edict permitting foreign physicians to practice and to teach in Rome. The outstanding contributions of several men to psychiatry during this period merit brief consideration:

In the 1st century B.C., Asclepiades, originally from Asia Minor, and a founder of the "Methodical" school, rejected the doctrine of vital fluids and built his theories on the atomic hypotheses of Democritus. He described phrenitis (as a fever accompanied by mental excitement) and mania (as continuous excitement without fever). Anticipating Esquirol, Asclepiades further differentiated illusions from hallucinations, and prescribed treatment in light rooms for patients afflicted with hallucinations because of their characteristic fear of the dark. Treatment also emphasized proper use of food and wine, physiotherapy and

other activities, which imposed minimal physical restrictions, and included such psychotherapeutic techniques as music and intellectual stimulation; finally, patients were encouraged to form emotional relationships with others.

In the first century, A.D., Celsus, the author of the classic eight-volume *De re medica*, dealt at length with mental diseases in Volume III of this impressive work. Essentially, the originality of Celsus' approach lay in the emphasis he placed on the value of the individual doctor-patient relationship. Celsus anticipated modern psychotherapy in that he proposed that such a relationship might evolve from the use of specific techniques to cheer depressed patients and quiet those who are manic; furthermore, he advocated the proper use of language and music and, possibly, some group activities, such as reading groups, as well. Thus, once again, passions were recognized as constituting the essential ingredient for the treatment of the mental patient.

Literary-philosophical concept. Cicero (106-43 B.C.) must be credited with the first detailed description of passions, which is included in his *Tusculanae Disputationes*, as part of his attempt to clarify psychological terminology. Having defined *animus* as corresponding to the Greek *psyche*, and *anima* to the Greek *pneuma*, Cicero proceeded to describe four main groups of *pate* (same root as "passions"), which can be translated literally as "perturbations." These included *aegritudo* (discomfort); *metus* (fear); *voluptas* or *laetitia* (pleasure, joy); and finally, the strongest of all, *libido* (violent desire). It was Cicero, then, who used the term "libido" in a psychological sense for the first time. Cicero further stated that excessive perturbation might give rise to *morbi*, actual diseases of the soul, and that, basically, they were caused by a contempt or abuse of "ratio," i.e., errors in judgment. In essence, then, the concepts elaborated by Cicero were based on the philosophical doctrine of Stoicism.

In contrast, Lucretius' (ca. 99-55 B.C.) *De rerum natura*, which exerted wide influence during the Middle Ages, followed the Epicurean doctrine. Lucretius conceived of both the mind (*animus*) and the soul (*anima*) as corporal and mortal. The mind was located in the breast—the seat of feelings and intelligence—while the soul was dispersed throughout the body.

Galen. Apart from his prolific writings on philosophy, Galen (ca. 130-200 A.D.) was undoubtedly the greatest physician of Roman times. His contributions to philosophy, as well as medicine, reflect the influence of Plato, Hippocrates, and the Stoics. Galen is best known for his theory of the spirits, which stated that the natural or physical spirits (carried by the blood, as a result of the digestive and reproductive functions) become transformed into vital spirits (in the veins and heart, under the influence of the circulatory and respiratory functions) and are finally transformed into animal or psychic spirits (through

a process of distillation occurring in the brain and the nerves). Like many of Galen's contributions, these concepts exerted a strong influence on medical thought and on Western thought in general, up until the time of the scientific revolution of the 17th century.

With specific reference to psychology, Galen attempted to disprove the Stoic dogma that psychological deviations (*pate* or perturbations) were due to defects of reason, which Cicero had ascribed to. Instead, he maintained that the health of the soul depended upon the proper harmony of the rational, irrational, and lustful parts of the soul. When errors in judgment were made unconsciously, they might be corrected by proper education. However, when such erroneous acts of judgment were reached consciously, for personal gain, they might prove more difficult, if not impossible, to correct. For obvious reasons, this distinction helped to remove much of the stigma attached to mental illness. From his treatise, *On Passions*, it would appear that the insight Galen acquired later in life into his own personal difficulties helped him to master his own passions. This accomplishment was due in no small measure to his relationship with a loved and respected mentor. Thus, it was his personal experience, in combination with his clinical experience, which fostered his understanding of the human mind.

Contribution to forensic psychiatry. It is in relation to the legal aspects of mental illness that the Romans made their most important contribution to psychiatry. Previously, the various terms which defined the mentally ill—*furiosi*, *mente capti*, *dementes* and *fatui*—had been used interchangeably. In contrast, the classic legal text of the late Roman times, the *Corpus Juris Civilis*, detailed the various conditions (insanity, drunkenness, etc.) which, if present at the time the criminal act was committed, might decrease the "criminal's" responsibility for his actions. Apparently, however, the state of mind of the defendant was determined by a judge; physicians were not consulted in such matters. And, for the most part, those persons who were considered to be mentally ill, including those who might be diagnosed as criminal psychopaths today, were placed under the custody of relatives or guardians appointed by legal authorities. In addition, laws were passed which defined the ability of the mentally ill to contract marriage, to be divorced by a spouse, to dispose of their possessions, to leave a will, and to testify. Finally, during the rule of the Emperor Justinian (483-565 A.D.), a number of mentally ill patients, for whom facilities had not been provided earlier, were admitted to institutions for the poor and infirmed, perhaps as a result of the influence of Christianity.

The treatment of mental illness. This more humane attitude toward mental patients, as evidenced in the philosophy of two great physicians of the time, is described by Caelius Aurelianus in his treatise, *On Acute and Mental Diseases*. The first of these,

Aretaeus of Cappadocia (1st century A.D.), who belonged to the pneumatic school of thought, described forms of melancholia which terminated in mania, thus anticipating the manic-depressive syndrome. Of particular interest is the psychological insight Aretaeus demonstrated in defining the influence of the emotions on mental functioning (e.g., love on melancholia). One hundred years later, Soranus of the Methodical school described the ideational content of mental disturbances and of various forms of "stupor." However, Soranus (1st-2nd centuries A.D.) is known, in particular, for the truly humanitarian principles he applied in the treatment and management of the mentally ill. Rooms were to be kept free from disturbing stimuli; visiting by relatives was restricted; the personnel responsible for the care of the patients were instructed to be sympathetic; during lucid intervals mental patients were encouraged to read and then to discuss what they had read, to participate in dramatic performances (tragedy was prescribed to counteract mania, comedy to counteract depression), and to speak at group meetings. And, of course, these procedures are basic to the therapeutic regimen in the modern mental hospital.

Essentially, other writers representative of this period of late Roman civilization and the early Middle Ages repeated the themes of classic antiquity in describing the treatment of mental disorders. In addition, three forms of melancholia due, in turn, to general physiological, nervous, and intestinal factors were described. The brain was considered of central importance in the causation of mental disorders: the forebrain was the site of disturbances of imagination; the midbrain gave rise to disturbances of reason; and the middle and the posterior part of the brain together were the locus for disturbances of thought affecting imagination and reason.

St. Augustine. Even today, one must be impressed by the originality of St. Augustine (354-430), to the degree that he is generally considered the greatest introspective mind before Freud. And his contributions appear more remarkable in light of the fact that he was not specifically interested in mental disorders. Nevertheless, his observations in many areas—on educational methods, on the nature of children, on the joy of being with friends, on the sense of power one derives from doing that which is forbidden—reveal great psychological insight. In each of these areas, various phenomena were attributed to sexual factors. It has recently been suggested that Augustine's preoccupation with sexuality was the result of his mother's strong attachment to him, on the one hand, and his unconscious admiration for his father, on the other. However, apart from their autobiographical value, his *Confessions* contain passages of great psychological significance; for example, the fact that Augustine's analysis of memory anticipated modern concepts of the unconscious is of obvious interest for psychiatrists.

St. Augustine accepted Cicero's description of four main passions, or "perturbations," namely, desire (i.e., libido), fear, joy, and sorrow, which could be moderated by reason. However, he qualified this by pointing out that if the soul is not "intent," that is, if there is insufficient motivation, then the effect of external agents, however powerful, remain unnoticed. This statement, which gives preeminence to the will, represents the essence of the voluntaristic Augustinian philosophy.

Psychiatry in the Middle Ages

When St. Augustine died, the Vandals were at the doors of his city of Hippo. A few decades later, in 476, the collapse of the western part of the Roman Empire signaled the beginning of a new era, the Middle Ages. Shortly thereafter, the classic civilization was overcome by younger forces which, after a period of social upheaval and intellectual stagnation, were finally able to create a foundation for the medieval world.

Theological influence. Initially, medieval man conceived of the world only in terms of God. It is no wonder, therefore, that mental diseases, like every other aspect of medicine, and science in general, received so little consideration. Concomitantly, abnormal phenomena were accepted as an intrinsic part of the total architecture of the world, a view which is directly opposed to the preoccupation of modern science with improvement and progress. This orientation may have had favorable repercussions as well, however. Although supporting evidence is not available, it appears quite likely that in a world which was considered to reflect the ideal harmony of a divine plan, the mentally ill would not be mistreated or neglected. Rather, they might conceivably be integrated into the community.

In this theologically oriented world, the peace of the cloisters and monasteries, where much of the classical heritage continued to be cherished and preserved, represented an ideal environment. Thus, the best minds of the time are to be found among the authors of the Patristic literature, which, at times, under the veil of moral and religious issues, dealt with psychological problems. To illustrate, John Cassian (360-435), who is generally considered the master of the Western ascetic tradition, in listing the qualities he considered conducive to inner perfection, included a description of the sorrow and melancholia which young monks suffered (*acedia*), which has a very modern—and existential—appeal. This tradition of ascetic literature culminated in the remarkable treatise on *Pastoral Care* by Gregory the Great (540-604), which delineated the clergyman's moral and religious role, and, in addition, emphasized the psychological understanding he must acquire in order to help his parishioners under stress.

The prevalence of mystic and occult beliefs. These enlightened views, however, were limited to a comparatively small group of spiritual and cultivated

people. The ignorant populations, which represented the great majority, were influenced by all sorts of mystic and occult beliefs, mainly of Eastern origin. In fact, there is evidence that even after the Christianization of the Northern countries, magical practices, which were carried over from the earliest Indo-European to the Anglo-Saxon cultures, continued uninterrupted. This has been substantiated by written records of charms, of ceremonies (involving idolatry; worship of daemons; the cult of the dead; worship of trees, stones, and fire; and augury and divination), and of similar events recorded by Bede and other historians. Thus, "devil" often meant "pagan deity," rather than "spirit of evil." Contests between saints and pagan magicians were reported; in many instances, Christian and pagan festivals coincided, and the cult of the pagan god was often replaced by that of the local saint.

The belief in witchcraft which was prevalent in the early Middle Ages has been related to the ceremonies which were held at night, and attended by women, for the worship of the goddess Diana. Apparently, these "women of the night" met primarily for the rather innocuous purpose of eating and drinking. However, the official attitude of the Church, as expressed in the *Canon Episcopi*, in 1147, was that these gatherings were an expression of deranged minds; that the women involved had worshipped devils, rather than pagan deities; and that they must be given religious sanctions accordingly. This attitude persisted until the 13th century when laws became more structured and the Inquisition was organized.

In regard to the treatment of mental illness, the extent to which pagan practices had survived is well documented by a report of the cases treated at St. Bartholomew's Hospital in London, written around 1180, and included in *The Book of Foundation of St. Bartholomew's Church*. The general belief was that mental patients were cured by supernatural forces, i.e., the intercession of saints. In fact, there was a similarity with the ancient practice of incubation, for such intercession was held to occur for the most part while the patient was asleep. When the saints failed to intervene, physical treatment methods, i.e., cathartics, emetics, and blood letting were used.

The Arabian contribution to psychiatry. A more humanistic attitude toward the mentally ill prevailed in Arabian countries, which may have exerted some influence on Western European countries as well. Actually, we have relatively little concrete knowledge regarding the attitudes of Arabs toward mental patients. However, we do know a great deal about the religious, ethical, and scientific forces from which such attitudes supposedly derived.

Some years ago, it was believed that the Arabs lacked originality, because their approach to mental diseases was largely influenced by Greek medical science, by the tenets of Christianity, and by the enlightened Byzantine administration. After they came

in contact in the 6th and 7th centuries with the scientists in Alexandria, and with the medical schools established by heterodox Nestorians and pagan philosophers in Syria and Persia, the Arabians translated into Arabic many Greek classic texts and, in turn, established flourishing medical schools. Furthermore, a number of asylums were founded in Baghdad in the 8th century, in Damascus in the 9th century, and in Aleppo, Kalaama, Cairo, and Fez in the 13th century. And, as early as the 12th century, travelers returning to Europe reported on the enlightened treatment mental patients received in these institutions. In his description of the psychiatric hospital built by Sultan Bajazet II in Adrianapolis in approximately 1500 A.D., the historian Evlija described in detail the relaxed atmosphere of this establishment, surrounded by charming fountains and gardens, and the therapeutic regimen, which included special diets, baths, drugs, perfumes, and concerts at which the instruments were tuned in a special way, so they would not "jar" the patients' nerves. Finally, an out-patient clinic and a medical school, where teaching was conducted in the Greek tradition, were attached to each hospital. The same treatment facilities were available to rich and poor patients alike, the majority of whom appear to have been manic-depressive psychotics.

At the root of this humanitarian attitude was the Moslem belief, stated by the Prophet, that the insane person is loved by God and particularly chosen by Him to tell the truth. Therefore, the difference between insanity and possession was conceived as minimal, and the mentally ill were frequently worshipped as saints. And, from a modern viewpoint, it would appear that this attitude might facilitate the patient's recovery, since it permitted free expression of his sexual and aggressive instincts. In any event, while the Arab approach to mental illness was influenced by Greek and Christian tenets and, in fact, was based on the mystical and superstitious tendencies of the Eastern Mediterranean countries, its application of these concepts was original and unique.

The school of Salerno. Of the four most important Arabian medical writers, Rhazes (865-925) and Avicenna (980-1037) came from Persia, and Avenzoar (ca. 1090-1162) and Averroës (1126-1198) came from Spain. The Arabs created a splendid civilization in Spain, with many learning centers, where Greek, Latin, and Jewish literature could be translated and thus become available to Western civilization. Certainly it is not surprising that in such a climate of liberal interchange of ideas, many scholars found it easier to accept an eclectic viewpoint. Among these scholars was Constantinus Africanus (ca. 1020-1087), who is recognized as the founder of the medical school of Salerno, near Naples, which enjoyed great renown in the late Middle Ages.

Like the treatises by his contemporaries and disciples, Africanus' *De Melancholia* was based on the amalgamation of classic and Arabian influences.

Typically, an excess of bile, which was attributed to an imbalance of the systems of the body, could cause melancholia. And, as was true in the past, the recommended treatment included proper diet, kind and sensible words, music, baths, cathartics, rest, physical exercise, and sexual gratification. However, Africanus' concept of two forms of melancholia was more indicative of his originality. According to this hypothesis, which became a basic formulation in 18th and 19th century literature, the site of the first form of melancholia was the brain; the site of the second was the stomach (hypochondriasis). He then proceeded, for the first time, to describe the symptoms which characterize this syndrome: sadness (due to loss of the loved object), fear (of the unknown), withdrawal (staring into space), delusions surrounding siblings and parents (which, today, would be attributed to ambivalence), and intense fear and guilt in religious people. Finally, Africanus advanced certain hypotheses regarding prognosis, which are generally accepted today: the prognosis was more favorable in acute reactive conditions and when the patient had not reached an extreme state of withdrawal.

The early Renaissance of the 13th century. The 13th century has been considered an early Renaissance, primarily because it brought about a more proper and realistic understanding of human nature (as typified by the poetry of Dante and the art of Giotto) and because the concepts formulated during this period preannounced the foundation of modern science. In the harmonious architecture of medieval knowledge, ascending from man to God, psychology was considered from a theological viewpoint. However, Aristotle's influence, imported through the Arabs and soon to become central to Christian philosophy, strengthened the biological foundation of psychology.

Psychiatric concepts of Albert the Great and Thomas Aquinas. Both Albert the Great (1193–1280) and Thomas Aquinas (1225–1274) were influenced by the views of Hippocrates, Galen, and the Arabians, according to which the body, conceived of in terms of the four classic elements, influenced all psychic phenomena, and the soul was the form of the body.

The psychic apparatus. The structure of the psyche was conceived of as comprising three levels—*anima vegetativa*, *anima sensitiva*, and *anima intellectiva*—a concept which anticipated Jackson's theory of integration.

The *anima vegetativa* referred to physiological functions.

The *anima sensitiva* was concerned with: (1) the external and the internal senses, including common sense (the inner center of the external senses), imagination or fantasy, memory, and the cognitive aspect of instinct, all of which originated in the brain; and (2) the *appetitus sensitivus*, which represented movement, i.e., the dynamic forces of the psyche, which lay somewhere between somatic and spiritual forces,

including lustful and irascible tendencies, and which, in a broad sense, would correspond to the sexual and aggressive instincts of today's psychology. These tendencies, which were located in the heart, were the source of all passions.

Finally, the *anima intellectiva* alluded to those qualities in the senses which enabled the cognitive functions of "ratio," i.e., judgment, and intelligence, which derived their impetus from the *appetitus intellectivus* or "will."

Theory of psychopathology. Central to the theory of psychopathology postulated by Albert the Great and Thomas Aquinas was the notion that the soul could not become sick. Therefore, insanity was primarily a somatic disturbance. Ultimately, mental disturbance was attributed to the deficient use of reason. And this, in turn, was due to one of two factors: either passions were so intense as to interfere with proper reasoning, or reason could not prevail because of the peculiar functioning of the "physical apparatus" (in dream states or states of intoxication, for example). Even the pathological character traits described by Albert, such as timidity, arrogance, resentment, impulsiveness, were attributed to somatic factors.

Both Albert and Thomas Aquinas described various psychotic symptoms (such as hallucinations) and different types of mental patients; these descriptions, though highly intuitive, show a lack of clinical experience. In addition to melancholia, (which he attributed to altered body humours), Thomas Aquinas described mania (pathological anger), organic psychosis (loss of memory), and epilepsy (which he attributed to an increased formation of vapors in the brain). His further elaboration of *stultitia*, *hebetudo*, and *ignorantia* correspond, respectively, to current concepts of the psychopathic personality, mental deficiency, and social retardation.

From a legal viewpoint, although mental patients (*amentes*) might have lucid intervals, they were incapable of distinguishing right from wrong; therefore, they could not be held responsible for any crimes they might commit. Sleep and baths were recommended treatment procedures. However, above all, neither Albert the Great nor Thomas Aquinas were immune to the beliefs held by other thinkers of medieval times, according to which both the cause and treatment of mental illness depended largely on astrological influences on the psyche, and on the evil power of daemons.

Other contributions to psychiatry. Of the other theories of the mind advanced during this period, those formulated by Petrus Hispanus (1200–1277), who, in 1276, became Pope John XXI (the only "psychologist" to achieve this honor), merit brief consideration. In fact, more than any other scholar of his time, Hispanus deserved to be called a psychologist. He viewed psychology as *pars nobilissima* of nature and maintained that the study of such phenomena

belonged to the realm of the natural sciences, rather than philosophy. Concomitantly, the *physicus*, whose efforts centered on the functioning of the psyche, was defined as a specialist in the fields of psychology and psychiatry. Passions, which Hispanus classified in accordance with Cicero's scheme, must be considered in relation to both psyche and soma. And within this framework, psychic disturbance was the result of multiple etiological factors. Thus, Hispanus foresaw, with remarkable accuracy, modern views of psychosomatic medicine.

Finally, Pietro d'Abano (ca. 1250–1316), the Averroistic philosopher who taught medicine, physiology, and astrology in Padua, anticipated some concepts of modern psychotherapy in his *Conciliator differentiarum*, which was published posthumously in 1476. For example, in discussing "enchantment" (*praecantatio*), he maintained that suggestion played a crucial role in the treatment of diseases. This technique might be particularly effective for those patients who were vulnerable to the physician's influence, provided he had the proper personality—kind, yet authoritative. In addition, in the tradition of Albert the Great and other thinkers of medieval times, Pietro d'Abano at-

tempted to evolve a scientific explanation of dreams by relating dream content to the personality of individual patients and to their "moral characteristics."

In summary, although the 13th century is generally considered a period of enlightenment in many fields of human endeavor (including the study of the mind), there is little evidence that any consistent effort was made to understand mental illness or evolve more effective treatment methods for such disorders. Moreover, this lack of comprehension of the nature of mental illness was to continue for several centuries. Consequently, throughout this period in history, mental illness remained untreated for the most part. Rather, mental patients were regarded as "characters" or, more kindly, as "poors" (which would seem to indicate a more tolerant attitude on the part of society than is evident in some segments of modern society). With regard to the status of mental health, in general, feudalism, with its rigid class structure, on the one hand, and the all-embracing architecture of the Church, on the other, provided a constricted system of controls. Within this framework, overwhelming sexual impulses could find expression only in the ideals of chivalry, while the religious wars and crusades served as an outlet for aggressive impulses.

Psychiatry in the Renaissance

Nevertheless, as early as the 13th century, it was evident that such a feudal society could not continue to exist, and in time this became increasingly apparent. But in the period preceding the ultimate decline of feudalism, the religious fervor on which it was based gave rise to a number of heretic movements and to a frank expression of collective psychopathology, as evidenced in the orgiastic dance frenzy or dancing mania of the Northern countries, in which sexual and aggressive instincts found gratification. Concomitantly, whereas feudalism emphasized the idealization of woman, which had been fostered by the Arabs and found expression in the romantic lyrics of the "troubadours" in Southern France, with the decay of medieval institutions woman began to emerge as a tempting and seductive being, who, from the time of the original sin, had been possessed by the devil and whose ultimate goal was the destruction of man.

The witchcraft mania. From this perspective, it is possible to understand the underlying motives which led to the full fledged mania—the open expression of misogyny—which flourished during the succeeding centuries. A physical explanation of some aspects of the witch has been advanced. For example, it has been suggested that hallucinations were caused by pharmacologically active ointments. In fact, however, the witch ritual represented a deliberate inversion and parody of the Christian way of life, designed to permit the free expression of repressed sexual and aggressive needs. The rise of the Inquisition helped indirectly to crystallize this ritual.

The *Malleus Maleficarum*, or "witches' hammer," by the two Dominican monks Sprenger and Kramer, which was published in 1487, 3 years after Innocent VIII's *Bulla* officially accepted the belief in demonology, inseparably linked mental disease and witchcraft for many centuries. Zilboorg has pointed out that this book was "so replete with sexual details that at times it may well be considered a handbook of sexual psychopathies." In any event, a person who became delusional or hallucinated was considered to be possessed of the devil, and to be a witch. And the *Malleus Maleficarum*, which has been described "as the most horrible document of that age," became the standard reference for Church and state alike in regard to matters concerning the indictment, trial, judgment, and punishment of alleged witches and went through 29 editions up to 1669. During this period, a number of sexual perverts, senile psychotics, schizophrenics, drug addicts, and psychopaths were falsely accused of witchcraft by the populace or were actually involved unconsciously in witchcraft practices through autosuggestion (see Figure 2).

A certain proportion of the mentally ill found an outlet for their pathological drives in war or religious manifestations, (e.g., crusades, pilgrimages, and heretic movements). However, other mental patients were confined to attics and cellars, where they were virtually imprisoned by their relatives, and still others, who were even less fortunate, were simply abandoned. Sebastian Brant's *Das Narrenschiff* (Ship of Fools), which was published in 1494, although it was meant to be satirical, provided an accurate picture of the prevailing attitude toward the mentally ill (Figure 3).

These developments, if they are to be clearly understood, must be considered in their proper context. This was a period in history when irrationality had an accepted place in the realm of human experience: perception was mainly auditory and tactual rather than visual, which frequently led to illusions and fantasies. And it was not yet man-oriented. Irrationality and madness were considered to play a definite role in the charismatic architecture of the world. Accordingly, the insane were represented on the stage in a stereotyped way, or they were considered, in the Arabian tradition, as "speaking the truth" (an attitude which was immortalized in Erasmus' *The Praise of Folly* in 1509).

First indications of social upheaval. However, under the influence of epidemics (plague), migrations, wars, etc., attitudes were changing at an even faster pace than had been anticipated. In literature, philosophy, and the visual arts, man was slowly becoming conscious of himself and developing a different view of the world as a setting for existence, rather than for his return to God. Although the rise of humanism in Italy in the 15th century and later throughout the rest of Europe is no longer considered an antireligious expression (which was the interpretation attached to

FIGURE 3. Instruments of torture for witches, many of whom were psychiatric patients. (From a German engraving of 1527 at the Cornell University Library. From Robbins, R. H. *The Encyclopedia of Witchcraft and Demonology*, p. 507. Crown, New York, 1959.)

these events in historical accounts of the 19th century), the fact remains that man's awareness of himself as an individual whose creation enhanced God coincided with the diminishing influence of the Church.

Changing attitudes toward the mentally ill. These new developments gave rise to concomitant changes in the attitude toward mental illness. In fact, by the 14th century, several institutions had already been established for the care or, more accurately, the custody of mental patients in Metz (1100), Uppsala (1305), Bergamo (1325), and Florence (1385). Furthermore, as is well known, the town of Gheel, in Belgium, had become a center for the care of mental patients during the Middle Ages, as a result of the miraculous renown that the Church of St. Dyphna—named after an Irish princess persecuted and killed there by her incest-ridden father—had acquired for the healing of many patients.

Pioneer treatment efforts. Traditionally, however, the founding of the first mental hospital in Valencia, in 1409, is attributed to Father Gilabert Jofré (1350–

1417), a Spanish priest. Legend has it that Father Jofré decided to enlist the help of his parishioners to build a hospital for the insane after he had witnessed a street scene of mockery and sadism toward the mentally ill typical of the customs of the time. Apparently, Father Jofré was sufficiently impressed by his experience to press toward his goal; his hospital was completed within the year. Moreover, in the period from 1412 to 1489, five similar institutions were established in various cities in Spain, and in 1567, under Spanish influence, the first mental hospital was established in Mexico City. Without question, then, the role of Spain in regard to the hospital care of mental patients, in both the Old and New World, remains of primary significance.

It is equally certain that the Arabs exerted a major influence in shaping the new attitude of the Spaniards toward mental patients. This is further borne out by the many similarities between these early mental hospitals and some of the Arabian institutions which, apparently, were devoted to mental patients, such as the one built by Mohammed V in Granada in 1365.

The emergence of humanism. Other influences were at work as well, and among these the revival by the humanists of the classic culture of Greece and Rome was of particular significance. The Spanish-born Luis Vives (1492–1540) is generally recognized as the most articulate and effective representative of the new trend of humanism. Vives spent most of his life in England and Belgium, where he advanced radical views on social welfare and on the education of women, in direct contrast to the prevailing misogynic trend. In *De anima et vita*, which Vives wrote in 1538, he dealt with the mind from an empirical viewpoint, stressed the emotional origin of certain associations, and even hinted at the role played by the instincts in human behavior.

The scholar Cornelius Agrippa (ca. 1486–1535) was even more outspoken in his opposition of misogyny. *On the Nobility and Pre-Eminence of the Feminine Sex* was written in 1509 as a general defense of women. Furthermore, in 1519, he underscored his beliefs by risking his life in Metz to liberate a woman who had been accused of alleged witchcraft.

In combination, these events, although described only briefly, clearly indicate the emergence of a new trend. There was an increasing tendency to take a fresh look at man, from the viewpoint of classic wisdom, grounded in the Christian tradition. The many treatises on family life and the education of children which were published in Italy during the 15th century may be regarded as a further expression of the gathering momentum of this humanistic—and human—outlook.

Johann Weyer: The first “psychiatrist.” Because of his books on the occult sciences, Agrippa was generally regarded as a rather controversial figure. Nevertheless, the benefits which were to derive from

the influence he exerted on Johann Weyer during his adolescence are universally acknowledged.

Weyer was born in 1515 in Graves, a town on the border between Holland and Germany, and later studied medicine in Paris, where he became acquainted with a number of scholars. After he had completed his medical studies (which were in the medieval tradition), until his death 38 years later, in 1588, Weyer served as personal physician to Duke William of Jülich, Cleves, and Berg. Although he would, undoubtedly, be considered an enlightened man by any standards, in later life the duke became mentally ill, and typically, this may explain his particular sensitivity to psychological issues, and his interest in Weyer's investigations in this area. One can only speculate as to the extent to which Weyer's efforts were influenced by Duke William. The fact remains, however, that Weyer gradually turned his interest from general medicine to the study of individual human behavior, and, in particular, to the study of women who had been accused of witchcraft. The conclusions he reached in the course of his investigations were ultimately incorporated into his *De Praestigiis Daemonum*, which was published in Basel in 1563. It is today universally recognized that this book represents a landmark in the history of psychiatry; as such, a brief summary of its content is clearly indicated.

Weyer began with a very adamant rejection of the belief in witchcraft and a strong condemnation of the clergymen who supported it. He then proceeded patiently to explain a variety of the so-called supernatural signs with which witches were usually identified, on the basis of pure medical knowledge, and, when such knowledge proved inadequate, as in the case of hallucinations, to attribute such phenomena to a combination of natural and supernatural factors. Since Weyer was a 16th century man, it is likely that he genuinely believed that the devil participated, to some extent and in some special way, in human behavior. His determination to “make clinical situations as clear as daylight,” and to proceed to a careful psychological examination of mental patients is all the more remarkable in the light of his personal convictions. Weyer had acquired extensive clinical experience which enabled him to describe a wide range of diagnostic entities, and associated symptomatology, including toxic psychoses, epilepsy, senile psychoses, nightmares, hysteria, and delusions, as well as paranoia, *folie à deux*, and depression.

However, it is in the realm of psychotherapy that Weyer's contribution to psychiatry is truly outstanding and unique. Thus, for example, he recommended that nuns in convents, who manifested psychological symptoms, frequently of an erotic nature, be isolated first and then permitted to return to their own families. But, above all, he insisted that the needs of the individual, rather than the rules of the institution, must be given primary consideration.

This attitude was further exemplified in an account of his treatment of Barbara Kremers, a 10-year-old girl who, supposedly, had existed for over a year without food or drink. Weyer moved the patient and her older sister to his own home, where they lived among his family. After a period of observation, he concluded that the patient's behavior represented an unconscious desire to malingering. The important point is that here, and elsewhere, he tried to initiate a new approach to treatment which was to provide the framework for modern psychotherapy. More specifically, on the one hand, Weyer recognized the importance of the therapeutic relationship, and of the kindness and understanding the therapist must extend toward his patient. However, he further postulated that, to be truly effective, this benevolent attitude must be based on scientific principles, i.e., careful psychiatric examination and observation.

Weyer's classic volume also included a discussion of matters relating to the trial and punishment of alleged witches, which represents an important contribution to legal psychiatry. And, finally, it presented his pioneer views on possible areas for collaboration between physicians and clergymen, and the benefits to be derived from such collaboration.

Weyer's radical approach was, of course, completely alien to the thinking of his times. As a result, his work evoked hostility initially, and then was simply ignored by theologians, philosophers, physicians, and lawyers alike—the very audience to whom his book had been directed. In fact, among the leading “demonologists” of the 16th and 17th centuries—Bodin, Delrio, Guaccius, Remy, King James I, Cotton Mather—only Reginald Scott, in his *Discovery of Witchcraft*, published in 1584, came to Weyer's defense. Weyer, himself, had expected that his book would encounter some opposition. However, he could not have anticipated that it would be listed in the *Index Librorum Prohibitorum* until the beginning of this century. Nor could Weyer have predicted that his observations would be disregarded by physicians who were mainly interested in mental disorders, or more specifically, in problems involving nosology, during the 17th and 18th centuries, and by those interested in organic pathology in the 19th century. Only recently, with the advent of dynamic psychiatry, was the historical significance of Weyer's contributions evaluated in proper perspective, thanks to the efforts of Binz and Cobben.

The humanism of Paracelsus and Cardan. As might be expected, Weyer remained without peer during the 16th century, in terms of the originality and imagination which are evident throughout his writings. Nevertheless, it would seem appropriate in this context to refer briefly to the views advanced by two other enlightened scholars of this period, Paracelsus and Cardan.

The famous Swiss-born physician Paracelsus (ca. 1493–1541) advocated a more humane approach to all

patients, including those who were afflicted with mental illness. In his book, *On the Diseases Which Deprive Man of Reason*, which was written in 1526 and finally published in 1567, Paracelsus clearly rejected demonology, made definite reference to the unconscious, and hypothesized that sexual factors played a role in the pathogenesis of hysteria and neuroses (which, according to Zilboorg, constituted the first definite statement to this effect). Because of the obscure nature and the lack of clarity typical of his writings, these views were the source of considerable controversy, which veiled their essential significance for psychiatry. Only recently were Paracelsus' contributions accorded adequate recognition.

Jerome Cardan (1501–1576), a mathematician, philosopher, and physician, was among the first to use his personal experiences as the basis for his efforts to understand psychological phenomena. In his *Autobiography*, which he completed in 1570, Cardan described in detail the emotional disorders which he underwent during his childhood (nightmares and stuttering, which he ascribed to his father's pathological influence) and as an adolescent (sexual impotence, hallucinations, and grandiose ideas). Cardan's son, who, in turn, was aversely influenced by his father's neurotic tendencies, became so disturbed in later life that, eventually, he killed his wife. Cardan's awareness of the psychological factors which he believed had precipitated his son's behavior led him to postulate (albeit not for the first time) that the mentally ill should not be considered responsible for their criminal acts, a view which is very similar to the later concept of “moral insanity.” Apart from his *Autobiography*, Cardan wrote a number of other works. At various times, in his numerous publications, he opposed persecution of people for so-called witchcraft, detailed the prerequisites for mental health, and, finally, described various character types and their somatic correlations.

Physiognomy and morphology, forerunners of modern character analysis. An attempt to correlate character type with somatic variables would properly include physiognomy, a field of study which became very popular during the Renaissance at the time of the “discovery” of anatomy by Vesalius (1514–1564), and the concomitant emphasis on man as a “microcosm” which reflected the “macrocosm.” In fact, however, physiognomy has a long history in the development of man, which can be traced back to the Arabs; to Pietro d' Abano, mentioned above; to Michael Scott, the 13th century astrologist of Frederick II; and to Michael Savonarola, grandfather of the famous proponent of Florentine religious reform.

Many volumes on physiognomy were published in the late 15th century, but none acquired such wide popularity as the *De Humana Physiognomia*, by Giambattista della Porta (1538–1615), the well known Neapolitan writer of scientific (or pseudoscientific) subjects. The main thesis of his book, which is presently termed “teriological physiognomy” was that the

physical resemblance of man to animals may be extended to apply to behavioral characteristics as well (for instance, sharpness of sight, cautiousness, aggression, etc.). Della Porta also attempted to support the validity of this concept by inserting numerous illustrations throughout his book, which have become justly famous. In a broader sense, however, physiognomy represented the culmination of a series of means of divination used by man. Initially, in early religions, magic traits were assigned to anthropomorphic gods, then in astrology to the planets and stars, and lastly, in physiognomy, to the parts of the human body (hand, head, etc.). Thus, physiognomy represents the final stage of a cycle which initiates and terminates with man. This final concept of man as the focus of the entire universe is crucial to Renaissance thinking and led to various currents of thought which, in turn, ultimately produced certain current theoretical trends, including the modern concept of the biological constitution in relation to psychological functioning.

As a result of his studies of the morphological constitution, the Spaniard, Juan Huarte (ca. 1530–1592), in his book, *The Examination of Men's Wits*, published in 1574, advanced the thesis that variations in the intellectual capacity of men may be attributed to differences in temperament. Thus, Huarte came even closer to modern character analysis and the concepts of vocational orientation.

The preeminence of scientific contributions to psychology. The contributions to psychology and psychopathology by Cardan and della Porta and the other physicians mentioned in this subsection must be considered a reflection of their ability as scientists, rather than clinicians. With the notable exception of Weyer, Renaissance clinicians, although renowned for their anatomical and physiological discoveries, added very little to our knowledge of human psychopathology.

To mention only some of the more outstanding among them, Girolamo Fracastoro (1483–1553), mainly known for his poem on syphilis, accurately described the anxious state of mind of melancholics and suggested methods for the prevention of suicide; Girolamo Mercuriale (1530–1606) related melancholia to a disturbance in the heart rather than in the brain; Jean Schenck (1530–1598) described various psychiatric signs, such as incubus, and manifestations of collective psychopathology (St. Vitus' dance, demonopathies); Konrad von Gesner (1516–1565), the well known scientist from Zürich, described several kinds of epilepsy and mental disorders, among which he included *amoris morbus* (the disease of love), and emphasized psychological aspects of dreams and the fact that they reflected the past, as well as present and future events.

The concepts advanced by each of these clinicians are lacking in originality. Nevertheless this quality did exist in Renaissance thought. To find it, one must go back to Leonardo da Vinci (1452–1519) who, even

before Galileo and Bacon, attempted to establish some kind of scientific methodology by means of various experiments involving man and his functions. His efforts included the careful study of the cerebral ventricles through injection of cadavers. In addition, he anticipated modern concepts of the functioning of the nervous system (Jackson's motor automatisms), and the Rorschach test by pointing to the individual reaction to the configuration of spots and clouds. He investigated the psychophysiology of perception (stereoscopic vision, binomial character of colors, persistence of images), the expression of emotions in physiognomy, and the emotional selectivity of memory. He hinted at the importance of self-suggestion (hypnotic fascination, especially in women) and of dreams. And, in general, he emphasized the instinctual component of the mind.

The layman's view of mental illness. Despite the advances in psychology and psychiatry, as outlined above, the fact remains that in the 16th century—at which point the Renaissance had reached its peak—the attitude of the general public toward mental illness remained essentially the same as the attitude which had prevailed in ancient and medieval times. It has frequently been pointed out that this phenomenon, which ultimately led to the psychiatric revolution of the 19th century, was due to the lag between persisting medieval social institutions, on the one hand, and individual creativity, on the other. It was this basic discrepancy which accounted for the lack of community responsibility and humanitarian attitudes which characterized this period.

As a result, there was no evidence of improvement in the facilities provided for the care of the mentally ill. When they were kept at home, their families frequently resorted to the use of chains. And, with few exceptions, the conditions to which the hospitalized mental patient was exposed were equally deplorable. Apparently, hospital administrators shared the popular view of mental illness, for until the 19th century,

FIGURE 4. Sketch of Bedlam (Bethlehem Hospital) by William Hogarth (1697–1764). (From *A Rake's Progress* (Plate VIII).)

mental patients were regularly placed "on exhibition" at Bethlehem Hospital in London, where they could be viewed by the public for only a few pennies; nor is there any indication that the Hospital of St. Maria della Pietà in Rome was an exception to the general rule, despite the fact that it was administered by a religious order established by the Portuguese Juan Ciudad (1495–1550), called John of God, and was dedicated to the care of all sick people, including those who were mentally sick (see Figure 4).

The layman's attitude toward the contemporary mental hospital was vividly described by the learned monk, Tomaso Garzoni (1549–1589), in *The Hospital of the Incurable Fools*, originally published in Italian in 1586 and translated into English in 1600, in which he presented a broad spectrum of psychiatric entities, ranging from alcoholism to melancholia, paranoia, and malingering. But apart from the stereotyped descriptions of the typical behavior of patients in each of these diagnostic entities, there is an occasional hint of Garzoni's awareness of their inner psychological condition, for instance, the longing for life and death, of the "insane for love."

Evidence of an awareness of inner struggle, reaching the highest level of existential pathos, is present to a much greater degree, of course, in many of Shakespeare's characters. Yet even Shakespeare attributed the so-called "Elizabethan malady," which is described with unwarranted frequency in English literature from the late 16th century to the middle 17th century, to the bodily humours (especially black bile) and, of course, to the influence of the stars. However, recognition of the importance of passions as an internal force, which, when it was not regulated by reason, could produce melancholia through the mediating action of the body, suggests that the foundation had been laid for a more modern view of a human psychological functioning as representing a continuum which ranged from normality to disease. Thus, the Renaissance picture of the "fool" slowly faded, and in its place modern conscience slowly advanced, as a concomitant of the Reformation, of pietism and other religious trends, of philosophical criticism, of early liberal tendencies, and in the new atmosphere of growing national entities.

Psychiatry in the Seventeenth and Eighteenth Centuries

The origins of modern medicine and science. The 17th century represents a period of transition from uncritical dependence on the ancients' belief in the gods, which in the Renaissance had found expression in the witchcraft mania, to the specification and application of methodological criteria in science. Galileo and Bacon must of course, be credited with the formulation of the basic criteria for scientific experimentation. The widespread application of their concepts may be attributed to the fact that they were elaborated in Latin, then the universal language of

science. In addition, the promulgation of these new theories may be ascribed to the establishment, in the years from 1657 to 1700, of the first four scientific societies (i.e., the Accademia del Cimento, The Royal Society, the Académie des Savants, and the Berlin Akademie) and the first professional journals (i.e., *Philosophical Transactions of the Royal Society* and the *Journal Des Savants*). Concomitantly, the Copernican revolution, by demoting earth from a central role in the universe, had paved the way for a more critical and objective view of the world, and, subsequently, of man himself. Obviously, the old beliefs in astrology and alchemy could not be expected to disappear overnight. However, these tenets now contributed to the foundation of the new sciences of astronomy and chemistry, which were further implemented by the many technological advances during this period. This new dynamic concept of the world was soon expanded to include man, and Harvey's description of the circulation of the blood in 1628 fostered this view. Subsequently, Santorio did pioneer work on metabolism; Malpighi, on capillary circulation; Redi, on the generation of life; and Bonet, on pathological anatomy; later, in the 18th century, Galvani developed his theories in physiology. Whatever their specific area of investigation, all these men shared certain interests in common: the forces which generate life, the nature of death, the study of microorganisms and of cells and chemical compounds as basic constituents of the human body. After the Greek word, *jatros*, for physician, these scientists were called jatro-physicists, jatro-chemists, or jatro-mechanics, depending on their particular focus.

New anatomical and physiological concepts of the mind. In psychology, a word coined in 1590 by the German philosopher Göckel (1547–1628), the emphasis was placed on those organs which mediated between passions and body humours, namely, on the body-mind relationship. The *sensorium commune* which was considered central to this relationship was variously located in the pineal gland (Descartes), in the corpora striata (Vieussens), in the centrum ovale (Boerhaave), in the corpus callosum (Lancisi), and, finally, in the medulla oblongata (Malpighi, Willis).

Réné Descartes. Of all these men, René Descartes (1596–1650) was undoubtedly the most important. Indeed, his philosophical postulate concerning the essential distinction between body and mind continued to influence psychology up to the beginning of this century and was responsible for the split between morphology and psychology. Descartes' theories were subsequently rejected because of their strict materialism. However, today, an increasing number of scientists no longer subscribe to this viewpoint. Thus, his attempt to locate the mind in the pineal gland is seen as a dynamic, rather than a static concept. Specifically, Descartes defined the seat of the soul as the site of its activity, rather than its locale, which implies that he conceived of the soul as a physical

force, *virtu*. He continued to subscribe to the Galenic concept of spirits; however, he related differences of temperament or natural propensities to differences in the number, size, shape and movements of the spirits. And he concluded that each reflex action reflected the total functioning of the nervous system. Furthermore, he maintained that movements, i.e., mental phenomena, could occur only after a rational soul had been joined to the body machine, a view clearly opposed to the concept of the "homme-machine," which many workers have incorrectly attributed to Descartes.

Traditionally, Descartes is considered the most outstanding representative of 17th century rationalism. Nevertheless, he attached great significance to emotional factors. This has been substantiated by evidence from still another source: obviously, one's life experience will inevitably be reflected in one's work. The fact that in his own life, Descartes was guided by strong emotions, as well as reason, is illustrated by his performance in two life crises. The first of these occurred when, at 17, he rejected the Jesuit teachings. The second occurred at the age of 23 when he had his three famous dreams, which several of his biographers have explained as "mystical crises." In any event, apparently, by the time he was in his fifties, his major conflicts were resolved for the most part, for in 1649 he was able to write the *Traité des passions de l'âme*, which consists primarily of his correspondence with his pupil, Princess Elizabeth of Bohemia.

The classification of mental diseases. As might be expected, these various scientific developments led to a preoccupation with the classification of mental disorders. Thus, the first medical textbook published in the 17th century to deal with psychiatry, the *Praxis Medica*, written in 1602 by the Swiss physician Felix Platter (1536-1614), begins with a 75 quarto page introduction on the classification of mental diseases. Like his contemporaries, Platter subscribed to a theory of organic humoral causation; however, this view did not necessarily outrule the devil as an etiological factor, at least in some cases of "possessed" female patients. Platter's contribution is historically significant. Undoubtedly, however, the two physicians who were most important for the history of psychiatry in the 17th century were Zacchia and Sydenham, who differed radically in orientation.

Legal psychiatry (Zacchia). Paolo Zacchia (1584-1659), who is generally regarded as the father of legal medicine, served as the Pope's personal physician for many years. In this capacity, he was called on frequently to give *consilia* to the Court of the Sacra Rota, the highest judicial body of the Catholic Church. In his lengthy volume, *Questiones medico-legales* (1621-1635), he presented many case reports and then made many recommendations, which would be considered valid even today. Zacchia's discussion of these cases began with a statement that in his opinion, only a physician was competent to judge the mental con-

dition of a person. He then suggested that such an examination should be based on observation of the person's behavior, language, actions, ability to exercise sound judgement, and, finally, emotional state. Mental disorders were classified as (1) *fatuitas* (which denoted the symptom complex generally associated with immature and psychopathic persons); (2) *insania* (comprising mania, melancholia and "disorders of passion"); and (3) *phrenitis* (which, for the most part, were considered to be organic conditions, in the hippocratic tradition). For persons in each of these categories, Zacchia outlined certain "rules" regarding imputability, ability to testify, to marry, to enter a religious order, to leave a will, etc. Above all, Zacchia's importance lies in the liberal attitude reflected in these concepts, which stressed that the person, rather than the law, was to be given primary consideration. Thus, manic patients who had lucid intervals could only be held partly responsible for their criminal acts; marriage might be beneficial for some melancholics, who could also hold positions with limited responsibilities. Individuals who committed "crimes of passion" should be acquitted; alcoholics should be studied carefully; epileptics should be made to undergo a period of intensive study and observation before they were accepted into religious orders. In cases of malingering, one should keep in mind that not all symptoms are known to the patients and can be reproduced by them. Finally, their melancholia led possessed persons to believe they were persecuted by the devil. This brief summary of Zacchia's concepts underscores his progressive viewpoint. Certainly, on the basis of his contribution, his name should, at long last, be removed from oblivion, so that he may assume his proper role in the history of psychiatry.

Advances in clinical observation (Sydenham). The second 17th century physician whose work was of particular significance for the history of psychiatry was Thomas Sydenham (1624-1689), who is generally considered to have initiated the clinical approach in modern medicine. Although Sydenham was not specifically interested in diseases of the mind, in the course of his clinical experience, he had become aware of the importance of neurotic and hysteric symptoms and the frequency with which they occurred among his patients. He described these symptoms in detail. He pointed out that, contrary to popular belief, hysteric manifestations were not restricted to women but might be observed in men and children as well. Moreover, hysterical illness might include a wide range of symptoms, such as vomiting, convulsive coughing, spasm of the colon, pain in the bladder and back, and retention of urine. Sydenham's therapeutic armamentarium in such cases did not extend beyond the usual methods of blood letting and the use of cathartics and emetics. Rather, his great importance derives from the fact that, whereas psychiatry had focused exclusively on psychotic phenomena, now, for the first time, attention was drawn to the symptoms of neurosis. This

new area of emphasis was not fully explored, however, until the beginning of the 20th century, largely as a result of the work of Sigmund Freud.

Throughout the 17th and 18th centuries, other workers adopted the clinical approach initiated by Sydenham for the observation and description of emotional disturbances. As a matter of fact, despite its initial significance, the classification of mental disorders had, in much the same way as Linnaeus' major opus in botany (1758), degenerated into a taxonomic compulsion. Rather, the advances in psychiatric knowledge achieved during these 2 centuries consisted specifically of isolated descriptions of symptoms and clinical pictures, which were often ignored or forgotten. In Zilboorg's words, "The original and refreshings parts of the literary contribution to medical psychology [of this period] are to be found in the ever increasing number of case reports, in the observations of certain psychological details which, even though not a little desultory, represent an important contribution and a remarkable step forward." This orientation was evident in the description by Charles Lepois (1611-1675) of postpartum psychosis; in the description by Herman Boerhaave (1668-1738), and particularly his successor Jerome Gaub (1705-1780), of psychosomatic conditions. It was from this viewpoint that S. A. Tissot (1728-1797) explored the problem of nervous diseases (epilepsy). It is reflected in a report by Sir Kenelm Digby (1603-1665) of a case of *folie à deux*; in the lengthy dissertation by Giorgio Baglivi (1668-1707) on tarantism. This attention to psychological detail led D. T. de Bienville (1726-1813) to introduce the term "nymphomania" in 1771 to describe "uterine furor." Similarly in 1733, George Cheyne (1671-1743) provided a detailed account of the "English malady," later known as neurasthenia. Furthermore, the "*maladie des vapeurs*," a favorite symptom of many fashionable ladies, came to signify hysteric symptoms caused by the spreading, to the upper part of the body and the brain, of noxious substances which supposedly emanated from the uterus; while "spleen" was attributed to the neurotic and hypochondriac disposition of the English people. In addition to the professional literature (John Purcell's *A Treatise of Vapours*, published in 1702; Richard Blackman's *A Treatise of Spleen and Vapours* which appeared in 1725), these terms were used widely in colloquial expressions.

A description of the melancholic disposition in the classic tradition is central to *Anatomy of Melancholia*, by Richard Burton (1577-1640), which was republished without interruption from the middle of the 17th to the 19th century. Not surprisingly, the real reference for Burton's description of melancholia was autobiographical, and his writing was prolix and discursive, rather than scientific. However, his elucidation of the psychological and social causes of insanity, e.g., jealousy, solitude, fear, poverty, unrequited love, or excessive religiosity, justifiably appealed to his con-

temporaries and their descendants. This emphasis on emotional factors in the causation of mental illness, combined with the rejection of supernatural factors and occult practices, marked a new stage in the development of a more humane and understanding concept of man, which anticipated the English liberal philosophy. This trend was similarly reflected in the spiritual and moral Christian guidance movement which developed during the 17th century as an expression of Protestant piety, and of the Catholic counterreformation and the religious orders which evolved from it. In brief, concern for the moral and spiritual welfare of the soul could not be divorced from consideration of psychological factors, as typified by the casuistry of the Jesuits, which was based on counseling and on establishing a relationship with the individual. On the philosophical level, the Jewish thinker Baruch Spinoza (1632-1677) provided the foundation for an integrated approach to physical and psychological phenomena, by considering them as two aspects of the same living organism; in so doing he anticipated some concepts of the dynamic unconscious.

Contradictions in the 18th century attitude toward the mentally ill. At the same time, however, as a result of the emphasis placed on reason during the *siècle des lumières*, madness was confined to the realm of the absurd and irrational, as beautifully portrayed in Molière's comedies. The glorification of reason, and the concomitant lack of tolerance for the irrational, by condemning and denying irrationality, culminated in a complete rejection of the mentally ill from a philosophical viewpoint, which represented the first step toward puritanism. Although passions were discussed to an increasing extent in the literary salons and in the lucid prose of the French moralists (La Bruyère, La Rochefoucault), they were also considered a great potential evil when they were not controlled by reason. And this ambivalent attitude was also conducive to a moralistic view.

In fact, during the 18th century, there was a basic contradiction in the attitude toward mental illness. On the one hand, the mentally ill were rejected by medical and other professional societies. On the other hand, the impressive scientific and social accomplishments during this period led to the establishment of modern science, and initial acceptance of the liberal ideas of Locke and Montesquieu, which ultimately laid the foundation for modern democracy in the 19th century. Thus, even as cultivated men all over Europe were engaged in philosophical discussion of the human mind and its functions, of social and economic theories, mental patients continued to be objects of ridicule and neglect. Although it is well known, Hogarth's painting of Bethlehem's wards in the eighth scene of his *A Rake's Progress* (1733) must be mentioned here as a representation of the customs of the time. Remnants of other primitive customs persisted as well. For example, the abolishment of capital punishment of sorcerers and witches by Colbert, Louis XIV's famous minister

in 1682, was considered to represent great progress. It did not eradicate superstitions and fanaticisms, however, as evidenced by the fact that 10 years later, there was a revival of the witchcraft mania in Salem, Massachusetts. There, within a single year, 25 alleged witches were placed on trial, and 19 were executed.

Admittedly, some dramatic forms of sadomasochism (such as the episode of the flagellants of Urban Grandier) were dying off. However, other forms of collective psychopathology continued to persist until their open expression on a major scale during the French revolution.

Institutional care of the mentally ill. Of course, as pointed out in recent literature, some progress was made in the understanding and treatment of mental disorders. For one, in 1744, more than 70 years after Lord Hale had differentiated total from partial insanity, an Act of Parliament established rules for the commitment of mental patients. In 1750, St. Luke's Hospital was opened at Moorsfield, England, and due to the influence of Benjamin Franklin, 6 years later, the Pennsylvania Hospital was established as the first public institution in the United States to accept mentally ill patients. In 1773, the Eastern Lunatic Hospital, for the exclusive treatment of the mentally ill, was opened at Williamsburg, Virginia, under the direction of the Galt family. The Elizabethan Poor Law Act of 1601, which placed the responsibility for the care of the poor—and frequently the insane—on local authorities, led to their exile from one community after another. The obvious inequities of this situation finally gave rise to some concern for the mentally ill and, concurrently, efforts to devise improved methods for their treatment.

However, even in the most progressive institutions, strong controversies raged between those physicians who believed that such treatment methods were of potential value, as opposed to those workers who believed that mental illness was, in fact, incurable. One such typical controversy occurred in 1758 between John Monro and William Battie at Bethlehem Hospital. In the light of present data these debates appear to have been highly unscientific. But they were, at least, concerned with concrete aspects of mental pathology, and far removed from the cold, formal classifications of mental disorders by Boissier de Sauvage (1706–1767) and Erasmus Darwin (1731–1802), the grandfather of the famous Charles Darwin. Certainly, they were more indicative of progress than the stand taken by Kant who, as late as 1798, in his *Anthropologie* continued to insist that the treatment of mental disorders was the proper province of philosophers, rather than physicians.

The influence of German "vitalism." G. A. Stahl (1660–1734), the German physician who was well known for his "phlogiston theory," attempted to superimpose the chemical orientation of 18th century medicine on the Aristotelian tradition. It was Stahl's contention that the soul was not a spirit, but a special

force, a drive characteristic of every living organism, a viewpoint which some workers regard as a direct antecedent of the psychodynamic theory of behavior. Similarly, C. F. Wolff (1733–1794), in his doctrine of epigenesis, stated that the living forces of the primary substance (protoplasm) shape each body organ. Both theories are representative of "vitalism," a trend which was particularly popular among the German romantics and enjoyed wide acceptance at the famous medical school in Montpellier, France, which had previously been influenced by Arabian, Jewish, and mystical concepts.

The British empirical orientation. On the other hand, in Britain, William Cullen (1710–1790) of Edinburgh, whose views reflected an empirical, philosophical orientation, acquired wide renown for his work in psychiatry, as well as other medical disciplines. In contrast to existing, more complicated classifications of mental disorders, Cullen defined mania as a disorder of the intellectual functions caused by an imbalance of nervous energy, which could be traced, in the last analysis, to the nervous system. Accordingly, treatment consisted in the decrease or removal of the nervous excitement, and opium was considered especially effective for this purpose. This trend was subsequently crystallized by John Brown (1735–1788), whose views were representative of the theory of stimulus and counter-stimulus, which later became a highly controversial issue in medicine.

The position of 18th century physicians in regard to psychiatry may be summarized as follows. No matter how enlightened their views might be in the abstract, these concepts were not actively applied to mental patients, who were kept at a distance and, for the most part, were still treated—or mistreated—in the manner of the Middle Ages and the Renaissance. Yet, some progress was made even in this area. As typified by Louis XIV, during this so-called period of "enlightened absolutism," the king of each European nation was idealized as a benign father figure who was responsible, not only for the safety of his subjects, but for their health, mental as well as physical. Accordingly, general hospitals for the care of elderly people, people with venereal diseases, epileptics, and the mentally ill, were built in several cities in France (in Paris, the Hôtel-Dieu in 1656). And, according to descriptions which have appeared recently in the literature, these installations combined the characteristics of a penal institution, an insane asylum, a sheltered workshop, and a hospital. Concurrently, the religious order of St. Vincent of Paul founded Saint Lazare in 1632, and the Brothers of Charity founded the Charité de Senlis in 1668, for the care of the insane and of "correctionnaires," namely, patients who today would be called juvenile delinquents, or psychopaths, primarily in need of supervision and rehabilitation. An elaborate system for the commitment of this patient category was instituted. Specifically, the family brought charges against the "correctionnaires" to the police, who, in

turn, verified the facts and obtained an order for their institutionalization (*lettre de cachet*) from the king. Thus, the king's responsibility was extended to include not only the general health of each family in his domain, but supervision of their moral standards as well.

Recent research on these charitable institutions has disclosed that both open and closed wards were provided for the patients, depending on their condition. In addition, there is evidence that they received both physical and psychological treatment, consisting of isolation, reading, personal interviews with the religious staff, spiritual exercises, and controlled contact with their family. A similar program, which appears to have been held in high esteem by such leading figures of the period as Voltaire, was instituted in some small institutions, the most famous of these, at the end of the eighteenth century, being the Maison Belhomme in Paris.

This serves to confirm that, as is the rule, there is never cultural fracture in history. Rather, there is progression, which may be so slow as to be completely obscure, but which, when rapid and innovating, takes on the features of a revolution. During the late 18th century, the general public became increasingly aware of the plight of the mentally ill and increasingly repelled by the fact that they were either completely neglected or, even worse, restrained by the cruelest methods, e.g., ropes, chains, etc. This reaction was a product of the individual and social conscience which was developing during this period—a conscience which had been shaped gradually by economic liberalism; by the new political principles of balance of power (Locke, Montesquieu); by educational reforms (Rousseau); by the development of science and technology independent of, or frankly opposed to, traditional religion; finally, by Voltaire's ironic view of the mores of the time. King George III's mental illness in 1765, which recurred in 1788, further highlighted many of the commonly used, brutal methods of restraint, from which not even a king might be spared.

Psychiatry during the Late Eighteenth and Early Nineteenth Centuries

Traditionally, the credit for the elimination of these objectionable methods of restraint has been ascribed to the French physician, Pinel, and his dramatic efforts to free the mentally ill from their chains at Bicêtre in 1793 have been described at length in the literature. While this should not be interpreted as a desire to engage in sterile controversy over priorities, the fact is that, more properly, Pinel should share the credit for this achievement with an Italian, Chiarugi, and an Englishman, William Tuke. Thus, here we have a striking example, indeed, of *Zeitgeist* in the history of psychiatry. Actually, the existing facilities for the care of mental patients had been criticized strongly in France in earlier reports by Colombier (1785), J. R. Tenon (1788), and La Rochefoucault-Liancourt

(1791). Furthermore, proper treatment methods had been proposed by the physician and philosopher, P. J. Cabanis (1757-1808), an illustrious representative of the school of the "ideologists," and author of *Rapports du physique et du moral* (1802). The French revolution outruled any attempt to initiate improvements in the existing institutions, but other equally important events occurred in Florence, Italy, in York, England, and even in France, in Chambéry and Paris.

Vincenzo Chiarugi. The rulers of Florence during the 17th and 18th centuries, i.e., the Medicis and the Lorenas, had continued to encourage the scientific research initiated by Galileo and carried on by others, especially in biology and medicine. Italian enlightenment, in contrast to that of the French and English, acquired a more practical character, which crystallized under the rule of the Grand Duke Peter Leopold (1747-1792) in a number of economic, financial, judiciary, educational, and religious reforms, culminating in the project for a constitution of 1778, a unique instance in which peaceful revolution almost led to modern democracy. Although many of these proposed economic and social reforms could not be put into effect by the Grand Duke and his ministers because the general population was simply not ready for them, several programs of importance to the future development of psychiatry were implemented.

The "law on the insane," which established the specific rules, including a mental examination, to be followed in cases of proposed commitment, was passed in 1774. In 1785, the Grand Duke began the construction of the Hospital Bonifacio, which was opened 3 years later, under the medical direction of a young physician, Vincenzo Chiarugi (1759-1820). The "Regulations" of the hospital (1788), which were obviously prepared under Chiarugi's supervision, specifically stated that "It is a supreme moral duty and medical obligation to respect the insane individual as a person." Accordingly, neither physical force nor cruel methods of restraint were to be applied to patients, except for the occasional use of a straitjacket, designed so that it would not cause the patient undue discomfort. Hygienic and safety measures were also described in the "Regulations," and, despite their unpretentious character, these represented a radical change in the treatment of the mentally ill. Chiarugi's three-volume work, *Medical Treatise on Insanity* (1793-1794), is somewhat obscure in those passages which describe the psychological foundations of personality (which represent an amalgamation of Aristotelian-Thomistic and modern concepts). Nevertheless, it is important for the pathological and clinical views. These volumes include descriptions of 100 clinical cases, accompanied in many instances, by descriptions of the condition of the patient's brain on autopsy as well. With regard to diagnosis, evaluation procedures were outlined, and mental illnesses were divided into three general categories: melancholia (partial insanity), mania (general insanity), and amentia (abnormal functioning of in-

FIGURE 5. Philippe Pinel (1745–1826), the founder of modern psychiatry, liberating mental patients at the Salpêtrière in 1795 (From the painting by Robert Fleury.)

telleet and will), which might be either congenital or acquired. The etiology of mental disease was discussed, and possible congenital and environmental causes were listed. Most important, the prescribed principles of treatment emphasized the importance of handling patients with tact and understanding, of using an authoritative and impressive but, at the same time, pleasant and individualized approach. Apparently, this therapeutic program, which was very similar to what was later known as “moral treatment,” was carried out by nurses and attendants, under medical supervision. Unfortunately, Chiarugi’s reform program fell into complete oblivion, first because of the peripheral role played by Florence on the European scene, and especially because of the preoccupation with the succession of wars and revolutions which took place throughout Italy shortly thereafter.

William Tuke. While these developments were taking place in Florence, the Society of Friends held a series of meetings in York, England, which were motivated by a desire to find ways of “mitigating the misery and restoration of those who are lost to civil and religious society.” Under the leadership of the elderly, but still vigorous, William Tuke (1732–1819), the “Retreat” was opened at York in 1796 for about 30 patients, who were treated as guests, with kindness and understanding, in a friendly atmosphere free from any mechanical restraint, and also from any direct medical influence. Rather, work of manual type was considered beneficial and greatly encouraged. This treatment philosophy was continued by William’s son, Samuel Tuke, and the Retreat served as a model for several institutions which were opened in this country in the early 19th century.

Pinel’s “moral treatment.” In the meantime, in

1791, Joseph Daquin (1733–1815), an obscure physician in charge of an institution at Chambéry, a village in the then French duchy of Savoy, had published the *Philosophie de la folie* in which he advocated a more humane approach to the care of the mentally ill. However, this contribution, like the work of Chiarugi and, to a lesser extent, William Tuke, was soon overshadowed by the renown that Pinel acquired throughout Europe. Philippe Pinel (1745–1826), was born in southern France and was influenced by the vitalism of the medical school at Montpellier. Later, when he moved to Paris, Pinel became part of the intellectual group of ideologists (Cabanis, D’Holbach). In 1793, after he had been associated with the Maison Belhomme for 5 years, Pinel became superintendent of the Bicêtre (for male patients) and later of the Salpêtrière (for females), where criminals and mentally retarded patients were housed, as well as the mentally ill. One of Pinel’s first accomplishments at the Bicêtre was, as mentioned above, to free the mentally ill from their chains. On the one hand, since he took this radical action during the Reign of Terror, this was widely acclaimed as an act of personal courage. On the other hand, its significance lies in its far reaching implications for the development of psychiatry. Pinel is remembered for two other major contributions to psychiatry: his attempt to analyze and categorize symptoms, and his application of “moral treatment.” Pinel described clinical symptoms in a very simple manner, but with great clarity, in the best medical tradition, as evident in his *Traité médico-philosophique sur la manie* (1801). More specifically, four types of insanity were described: (1) melancholia (disturbance in intellectual functioning); (2) mania (excessive nervous excitement with or without delirium);

(3) dementia (disturbance in thought processes); and (4) idiocy (obliteration of intellectual faculties and affects). Detailed data were accumulated for each patient, most of which were gathered by Pinel himself, a fact which accounts for the abundance of clinical examples throughout the book. More important than environmental factors were those factors which were considered to indicate a predisposition to the later development of insanity, and among these "passions" were considered of particular importance. Accordingly, moral treatment was based on Aristotle's concept of mental health as dependent on the balance of "passions," a term which, in 18th century literature corresponded to our present use of the term, "emotions." Moreover, in anticipation of later theories of psychosomatic functioning, passions (i.e., emotions) were considered the "link" between mind and body. With regard to specific therapeutic techniques, initially, the doctor had to exert the greatest firmness in his approach to the patient and hold his attention and control his will with his eyes. Once the patient was subdued and had been completely dominated by the doctor, treatment consisted of a combination of kindness, firmness, and coercion. While his book emphasizes this phase of treatment, which Pinel conducted with the assistance of his remarkable male nurse Poussin, there is evidence that the patient's participation in various activities within a structured environment greatly contributed to the success of Pinel's moral treatment (see Figure 5).

An overview of early contributions to psychiatric reform. Comparison of the therapeutic orientation of Chiarugi, Tuke, and Pinel reveals that each of these pioneers in psychiatric reform emphasized the healthy part of the patient's personality, i.e., to use modern terminology, the "conflict-free sphere of ego functioning." In addition, they shared in common the belief that any meaningful therapeutic approach had to be geared to the healthy part of the personality and that, consequently, the right treatment consisted of a combination of support and dependency. The course of treatment might be affected by the nature of the doctor-patient relationship (i.e., the transference), but, without exception, the treatment success required that the patient be separated from his family so that he might receive therapy in the structured environment of the hospital. Apart from these basic similarities in viewpoint, as mentioned earlier, Chiarugi's innovations were made possible by the various reform measures introduced by the Grand Duke Leopold, which implies a close connection between politics and psychiatry. Today, the desirability of such a connection would be debated at length. In fact, however, Chiarugi was practically unaware of the importance of the therapeutic reforms he initiated. Rather, he felt that the value of his work lay in his emphasis on the study of the anatomical changes in the brain of mental patients. William Tuke's innovations expressed his religious conviction that if mental patients were re-

moved from environmental stress, they would improve in the natural course of events. Treatment consisted only of a kind approach, devoid of any medical procedure. Finally, Pinel too, believed that mental illness was curable. However, his optimism derived from the influence of the French ideologists, rather than religious principles. Furthermore, the fact that his efforts coincided with the French revolution and the achievement of political equality of all citizens strengthened his belief. But whatever its philosophical basis, Pinel's over-all approach was so sound that moral treatment was accepted as the treatment of choice, thus initiating a new and fruitful trend in psychiatry.

Mental hospitals and the application of moral treatment in the United States. The United States constituted an ideal testing ground for some of these new ideas. Benjamin Rush (1745-1813), who is considered the father of American psychiatry, had been influenced by his early medical training in Edinburgh, where he studied before he became a professor of chemistry and then of medicine at the Philadelphia College. As one of the men who signed the Declaration of Independence, Rush was interested in all kinds of social reforms (temperance, abolitionism, etc.), and he introduced new methods based on moral treatment at the Pennsylvania Hospital. However, in his book, *Medical Inquiries and Observations Upon the Diseases of the Mind*, which was published in 1812 (and remained the only American textbook on psychiatry until the end of the century), Rush reaffirmed his belief in the therapeutic efficacy of purgatives, emetics, and blood letting, as well as in the "tranquilizer," a special chair in which agitated patients were seated, tied down, and then suspended in mid air.

More directly dependent on the new moral treatment were a number of small private mental hospitals, which were established in this country early in the 19th century. These included the McLean Asylum in Massachusetts, which was founded in 1818 under the supervision of Rufus Wyman; Bloomingdale Asylum in New York City (1821), under Thomas Eddy; and the Hartford Retreat in Connecticut (1824), under Eli Todd. Furthermore, during the 3rd and 4th decades of the century, 10 state institutions were opened, the most important of which were the State Lunatic Hospital at Worcester, Massachusetts, in 1833, under Samuel Woodward; the Pennsylvania Hospital for the Insane at Frankfort, Pennsylvania, in 1841, under Thomas Kirkbride, and the New York State Hospital at Utica in 1843, under Amariah Brigham. These three men, together with 10 others, were the "Original Thirteen" who constituted the Association of Medical Superintendents of American Institutions for the Insane, which was founded in 1844 and, as such, represents the oldest medical society in this country. And during the same year the *American Journal of Insanity*, currently known as the *American Journal of Psychiatry*, was founded (see Figure 6).

FIGURE 6. Signatures of the original 13 founders of the American Psychiatric Association, 1844.

Of the Original Thirteen, Isaac Ray (1807–1881) achieved preeminence on the basis of his *Treatise on Medical Jurisprudence of Insanity*, published in 1837, which has remained a classic in the field; Thomas Kirkbride's (1809–1883) fame derived from a manual he published in 1854 on the construction and organization of hospitals for the insane in which he advocated treatment of a maximum of 250 patients at any given time within any given hospital. It is not surprising that the superintendent of an institution with such a small patient population would represent a father figure to the patients and thereby facilitate the implementation of the principles of moral treatment even more successfully than was possible in Europe, under the impetus of the democratic spirit of this newly established country. In fact, the optimistic view of this treatment modality became so prevalent, especially at the Worcester State Hospital, that it gave rise to the so-called "cult of curability," a concept which was strongly opposed by Pliny Earle of the Bloomingdale Asylum.

To return to concurrent developments in Europe, two independent movements, somewhat opposed but equally appealing to many laymen, namely, phrenology and mesmerism, reached the peak of their popularity in the early part of the 19th century.

Phrenology. Franz Josef Gall (1758–1828), the founder of phrenology, was a distinguished physician from Vienna who taught brain physiology there for several years. On the basis of physiognomic concepts, especially those developed by the Swiss pastor, Johann Kasper Lavater (1741–1801), who was a close friend of Goethe, Gall postulated that mental faculties were innate and that they depended on the topical struc-

tures of the brain, to which corresponded particular protuberances of the external cranial surface. Eventually, he identified 27 organs in the human brain (19 of which were found in animals as well). These organs corresponded, in turn, to an equal number of faculties which, being fixed from birth, could not be modified by education. Although Gall tried to avoid criticism by theologians by including among the faculties he listed such factors as goodness, religious sentiment, etc., he was accused of materialism nevertheless and ultimately was forced to leave Vienna for Paris, where he was influenced by the ideologists. In Paris, he continued his neurological studies, in the course of which he anticipated the concept of cerebral localizations which were to prove so fruitful for future investigators. His phrenological teaching was carried on by his pupil, Johann Casper Spurzheim (1776–1832), who lectured extensively on phrenology in this country, where the new doctrine had already been introduced by two Scottish laymen, George and Andrew Combe. Eventually, phrenological societies and journals were founded in several American cities, and the movement became increasingly popular, owing to the efforts of its two principal proponents, the Fowler brothers. It did not decline in popularity until the latter half of the century.

Mesmerism. The second movement, mesmerism, was initiated by Franz Anton Mesmer (1734–1815), who, in 1766, in his doctoral dissertation at the University of Vienna Medical School ascribed to the concept that planets influenced physiological and psychological phenomena, a concept which derived from the writings of some Paracelsists (e.g., Robert Fludd) and others (William Maxwell, Richard Mead). In a later publication, entitled *Memory on the Discovery of Animal Magnetism* (1779), Mesmer hypothesized that man was endowed with a special magnetic fluid, a kind of sixth sense, which, when liberated could produce amazing healing effects. Mesmer, himself, claimed to have "magnetized" and "cured" many patients, but the controversy which arose over his treatment of Miss Paradis (a gifted musician who, quite possibly, had been afflicted by hysterical blindness) forced him to leave Vienna and move to Paris in 1778. There his miraculous cure achieved great success and, as a result, he elicited the support of many distinguished and wealthy people—and an equal amount of opposition from the medical profession. A Royal Commission which was appointed in 1784 and included Benjamin Franklin, investigated mesmerism and handed down an unfavorable report. Following this defeat, later on Mesmer retired to Switzerland where he died in poverty and oblivion. However, his pupils continued to practice mesmerism, and eventually the Marquis du Puységur (1751–1825) came to the conclusion that mesmerized patients were actually in a trance state. This observation was confirmed subsequently by James Braid (1795–1860), who coined the word "hypnosis." Even as the teaching of mesmerism flourished

in Germany, the physicians James Esdaile (1808–1859) and John Ellioston (1791–1868) made good use of mesmerism as a method of anesthetizing surgical patients in India and England, respectively. The importance of mesmerism for psychiatry lies in the fact that it represented the most notable attempt to focus on neurotic phenomena, as opposed to the exclusive preoccupation with psychoses.

National trends in psychiatry. While phrenology and mesmerism were gaining in popularity during the first half of the 19th century, academic psychiatry was taking its first steps. As the various national entities began to take shape in Europe at the end of the Napoleonic era, medicine in general, including psychiatry, began to acquire definite characteristics in each country. Thus, at this point in its history developments in psychiatry can best be understood within the context of specific cultural and medical trends which influenced scientific development in particular nations. In general, during this period, psychiatry gradually achieved recognition as a separate medical discipline. The term “psychiatry” was first used in specific journals devoted to this area of study, which were founded in Germany at the beginning of the 19th century but, unfortunately, were short-lived.

The French school. In France, where the most important developments occurred, psychiatrists stressed the clinical study of the patient, that is, the clarification of symptoms and their detailed description; the close relationship between psychiatry and neurology; and the medicolegal aspects of psychiatry. Concomitantly, a continuous effort was made to improve institutions and hospitals for the mentally ill. Among the members of this school, the contributions of Jean Etienne Esquirol (1772–1840), who was Pinel’s favored pupil, were particularly significant. Esquirol’s textbook *Des maladies mentales*, which was published in 1837, soon became a classic because of its clarity and the inclusion of statistics in the presentation of clinical matters (see Figure 7).

In brief, Esquirol clearly defined hallucinations and “monomania” (a symptom which is currently termed paranoid ideation); emphasized the role of the emotions in the etiology of mental illness; instituted programs involving group activities in various mental hospitals; taught the first course on psychiatry in 1817; and, finally, was largely responsible for the “lunacy bill” of 1838, which delineated commitment procedures for prospective mental patients, and influenced similar legislation in other countries.

Of the other members of the French school, Ferrus was outstanding for his interest in occupational therapy and his efforts to isolate the criminally insane; Falret, for his description of cyclic insanity (*folie circulaire*); Baillarger, for his studies of hallucinations (including alcoholic hallucinations); Voisin, for his book on idiocy (1843), which subsequently became a classic; Georget, for his unitary concept of mental diseases; and Leuret, for his work on thought processes

which anticipated the concept of schizophrenic dissociation. In addition, of particular importance are Bayle and Calmeil, for their description in 1826 of the psychiatric symptomatology of general paresis; Edouard Séguin (1812–1880), for his pioneer work on mental deficiency which he continued after he arrived in this country in 1848; and Moreau de Tours (1804–1884), for his experimental use of “hashish” which anticipated modern phenomenological views and the existential approach. Most of the papers by these or other psychiatrists were published in the *Annales médico-psychologiques*, which was founded in 1843.

The German school. During this time, German psychiatry was strongly influenced by the Romantic movement and by theological principles. On the one hand, the Reformation gave rise to a “personal piety,” which retarded the separation of medical psychology from theology. On the other hand, Stahl’s “vitalism” helped to focus attention on global and teleological aspects of psychological phenomena. Obviously, this focus, in itself, would raise no objection. However, in combination with theological tenets, it had unfavorable implications for the progress of German psychiatry. More specifically, German psychiatrists during this period had very little actual clinical experience. Their writings lack scientific objectivity; although there is occasional evidence of good insight, for the most part, such insights are blunted by sentimental pathos, and religious and metaphysical expressions.

Nevertheless, there were exceptions. With regard to the contributions of individual members of the German School, Heinroth, the first psychiatrist to use the word "psychosomatic," stressed the unity of mental phenomena (i.e., total personality). He attached particular importance to psychological conflict, which he identified as the cause of guilt, and ultimately, of mental illness. In this respect his views were not too removed from those of Ideler, who defined passions as the sum total of man's biological strivings, or of Groos, who attributed mental diseases to the frustration of man's drive toward self-expression. On another level, Heinroth contributed to progress in the institutional care of the mentally ill by defining the role of the physician and various members of the ancillary staff in this therapeutic setting. Of particular importance was Johann Christian Reil (1759-1813), who described psychoneurotic states, including the patient's penchant for introspection, and outlined psychotherapeutic methods designed to engender strong emotions (e.g., fear, disgust, pain) in the patient by means of various carefully planned devices, including theatrical performances. Of equal importance was Johann Gottfried Langermann (1768-1832), who built a modern mental hospital in Bayreuth, southern Germany, in which methods of restraint were abolished. In this connection, it should be mentioned that several German physicians of this period, such as C. F. S. Hahnemann (1755-1843), the founder of homeopathy, did make a determined effort to treat psychotic patients with kindness and understanding and attributed their improvement to this approach. Finally, Ernst von Feuchtersleben (1806-1849) presented views in his *Principles of Medical Psychology*, published in 1845, on the relationship between psychological and physiological phenomena, on the biological unity of the organism, and on the importance of psychotherapy in the treatment of mental diseases, which would be considered advanced even by today's standards.

In sharp contrast to the trend followed by the psychiatrists just mentioned, other psychiatrists during this period, Friedrich Nasse, Johannes Friedreich, and Maximilian Jacobi, by postulating direct causal relationship between mental illness and brain pathology, became the first proponents of the organic orientation in psychiatry which prevailed during the 2nd half of the 19th century. Friedreich was also responsible for some important studies on the history of psychiatry; and Jacobi published a book on the construction of mental hospitals which was widely circulated throughout Europe. The *Allgemeine Zeitschrift für Psychiatrie* was the most important German journal of that period.

The British school of psychiatry. During the 1st half of the 19th century, British psychiatry was characterized, in particular, by a practical orientation, as evidenced, for example, by the well built hospitals provided for mental patients. This was in accordance with the respect for the individual which was emphasized in the English philosophical works of the period.

As mentioned above, the traditions of the York Retreat were continued by William Tuke's son, Samuel Tuke, who outlined the policy which governed the operation of that institution in a volume entitled *Description of the Retreat*, which was published in 1812. Ten years later, in 1823, *Sketches in Bedlam* was published by an anonymous author (generally believed to have been influenced by the "apothecary," John Haslam) who strongly criticized patient care facilities at Bethlehem Hospital. John Conolly (1794-1866) while he was superintendent of the Hanwell Asylum, abolished the use of mechanical restraints at that institution and described his therapeutic approach in a volume entitled *Treatment of the Insane Without Mechanical Restraint*, which, on publication in 1839, was the subject of heated debate both in Great Britain and in this country. Eventually, however, as a result of the interest and support of Robert Hill, who was associated with Lincoln Asylum, Conolly's method gained increased acceptance. Furthermore, as a consequence of mounting interest in legislation pertaining to the mentally ill and especially with regard to commitment proceedings, application of the concept of "moral insanity" developed by James C. Prichard in 1835 became increasingly widespread. Prichard defined this term as an intellectual deficiency which was not accompanied by delusions or hallucinations, and which, as such, corresponded to the French *folie raisonnée* or *folie lucide*. As far as periodical literature is concerned the *Journal of Mental Science*, known today as the *British Journal of Psychiatry*, was the outstanding publication at that time.

Other developments in European psychiatry. As to developments elsewhere in Europe during this period, the contributions of two men were particularly outstanding. First, the Italian layman Pietro Pisani (1760-1837), who was superintendent of the mental hospital in Palermo, applied advanced methods of treatment which anticipated our current concepts of milieu therapy. Second, the Belgian Joseph Guislain (1797-1860) became well known for his textbooks and for his many activities on behalf of mental patients in his own country.

In summary, developments in psychiatry during the 1st half of the 19th century, while often idealistic and prescientific, played a significant role in building the foundation of modern psychiatry. It is difficult to delineate the many trends which influenced psychiatrists of that period. Nevertheless, many current psychiatric concepts may be traced back to the concerns which dominated psychiatric thinking at this phase of its historical development.

The History of Psychiatry from the Second Half of the Nineteenth Century to the Beginning of the Twentieth Century

During the 2nd half of the 19th century, science and technology made tremendous progress, and Western civilization acquired the industrial orientation which is characteristic of our own era. As the people of such

nations as Germany and Italy rebelled against their ruling dynasties and acquired political independence, a zeal for social reform replaced the former preoccupation with religion. And, concurrently, idealism and materialism became the prevailing trends in philosophy. Concomitantly, medicine became increasingly scientific and materialistic, and, as might be expected in this context, psychological phenomena came to be attributed to physiological factors. Partly as a result of the excellent universities which were established in many cities, Germany was the center of these new developments in science and medicine.

The prevalence of organic concepts. In psychiatry, Wilhelm Griesinger's (1817–1868) *Pathology and Therapy of Mental Diseases*, which was published in Germany in 1845, was soon considered the most authoritative textbook in this field. Griesinger maintained in essence that mental diseases could be explained only on the basis of physical changes in the nervous system. However, he also advanced views which anticipated recent developments in ego psychology and which justify our current interest in his work. Apart from such considerations, which are based mainly on hindsight, Griesinger's organic approach was adopted by other leading German psychiatrists, such as Leidesdorf, Westphal, and finally, Meynert, who earned a place in history primarily because he was one of Freud's teachers. This orientation was reflected in the descriptions of various clinical entities during this period, i.e., hebephrenia, by Hecker in 1871; catatonia, by Kahlbaum in 1874; and polyneuritis caused by alcoholism and severe deficiency of food intake (i.e., Korsakoff's syndrome), by Korsakoff in 1887.

Changing attitudes regarding the treatment of mental illness. The prevailing trend in the treatment of the mentally ill during this period consisted of the immediate separation of such individuals from their families and their prompt hospitalization in large institutions. Perhaps this trend was most evident in this country, where it was fostered by Dorothea Lynde Dix (1802–1887), a former school teacher, who throughout her lifetime devoted her efforts to persuading the legislative bodies of the various states to construct large mental hospitals. Miss Dix's efforts were motivated by a desire to involve the states directly in the care of the mentally ill, and certainly such direct participation was necessary in this country following the influx of large groups of immigrants from Europe. However, this movement acquired further impetus from other factors. For example, puritanic influences which eventually produced the Victorian attitudes characteristic of this period certainly contributed to the trend of separating mental patients from the rest of the population. It is not surprising, under the circumstances, that moral treatment, which, as mentioned earlier, was based on personal contact between the superintendent of the hospital and a fairly homogeneous group of patients, in terms of their social and ethnic origins, was discarded completely.

Instead, the treatment of psychiatric patients became increasingly impersonal, and in this climate, the organic view came to prevail. That is, mental illness was considered physiological in origin, and independent of "personal" and social factors.

The "degenerative stigmata." In its extreme form, this viewpoint found expression in France, in the work of Benedict Morel (1809–1873) and Valentin Magnan (1835–1916), who postulated that mental disease was evidence of a degenerative hereditary strain which would become progressively severe in successive generations, causing their extinction. In Italy, Cesare Lombroso (1836–1909), considered the founder of criminal anthropology, was particularly impressed by the degenerative stigmata and "atavistic types" of delinquents, and, in general, of all sorts of people who demonstrated a wide range of physical and psychological abnormalities. Furthermore, some psychiatrists, (including Lombroso) were preoccupied with the relationship between genius and insanity, which led, in turn, to a spate of "pathographies," among which those written by the German Möbius (1853–1905) were particularly important. However, the main psychiatric literature of the time and particularly the works of Krafft-Ebing (1840–1902) and Forel (1848–1931) reflected the concerns which occupied the Victorian mind, i.e., the influence of noxious factors (sex, alcohol, infections, industrialization, and social progress) on personality.

Somewhat in contrast to the trends discussed above, British psychiatry focused on clinical, rather than moral issues. Daniel Hack Tuke (1827–1895), the last representative of the Tuke family, became particularly well known for his dedication to the improvement of the care of the mentally ill and for his important writings, published in the period from 1858 to 1892 (*Manual of Psychological Medicine, Illustrations of the Influence of the Mind Upon the Body*, and *Dictionary of Medical Psychology*), in which he anticipated some modern views.

Psychiatry in the United States in the late nineteenth century. In this country, the Willard Act, which was enacted in 1865, provided for the removal of chronic insane persons from country poorhouses to state asylums and thereby gave further impetus to Dorothea Dix's crusade for the creation of large institutions. Eventually, chronic patients were separated from those whose prognosis was more favorable. As in Europe, those patients who seemed to show signs of improvement were assigned to "colonies," "farms," and even to "foster families." A State Commission of Lunacy was established in New York in 1873, and later in other states, and the term "hospital" was substituted for "asylum." However, although these events appear, at first glance, to indicate great progress, in fact, the medical staff of these mental hospitals had no contact with medical schools, nor were they interested in research, as a general rule.

The contribution of neurology to psychiatry. The effect of the large number of medical casualties during

the Civil War was to focus attention on the importance of neurology. Apart from their contributions to this discipline, William Hammond, E. C. Spitzka, and S. Weir Mitchell were the neurologists whose names are most frequently associated with progress in psychiatry during this period—Hammond and Spitzka for their textbooks on psychiatry, Mitchell for his outspoken criticism of the isolation of psychiatry from medical research (in a famous address before the American Medical Psychological Association in 1894), and for his “rest cure” method, which he considered particularly beneficial in the treatment of neurotic women (and which was a logical outgrowth of the concept of neurasthenia, developed by George Beard in 1880). Also, as a reaction to Mitchell’s criticism, a few psychiatrists became interested in research, and this led to the founding in 1895 of the Pathological Institute of New York Hospital (which later became the New York State Psychiatric Institute). A few years later, in 1902, the young Swiss psychiatrist Adolf Meyer (1866–1950) was appointed to the staff of the Institute where he remained until 1913, when he became director of the newly built Henry Phipps Psychiatric Clinic at The Johns Hopkins University. By that time, important “psychopathic hospitals” for training and the active treatment of patients had been established in Michigan (1907) and in Boston (1912), the latter under the supervision of E. E. Southard, who is noted for his pioneer views on the importance of social work for psychiatry.

The mental hygiene movement. One other event during this period was of particular importance for the development of psychiatry: Clifford Beers, a distinguished businessman, following his recovery from a mental breakdown, published his famous book, *A Mind That Found Itself*, in 1908 and in so doing launched the mental hygiene movement. Despite the implications for organic psychiatry of Noguchi’s and Moore’s discovery of *Treponema pallidum* in 1913, a social orientation was soon to prevail, and this, in turn, was followed by dynamic psychiatry, with its emphasis on the psychological functioning of the individual.

Kraepelin’s contribution to psychiatry, and modern organic therapies. Although he was Freud’s contemporary, Emil Kraepelin (1855–1926) can be considered the last representative of the predynamic school of psychiatry. A very industrious and academically oriented researcher, Kraepelin’s textbook on psychiatry was revised many times after its first edition in 1883 and reflects the transitional aspect of psychiatry over 4 decades. More specifically, Kraepelin’s main contribution was to differentiate between manic-depressive psychoses and dementia praecox, although this differentiation was unfortunately carried one step further than necessary, in that patients in the latter group were now included among the incurable. In fact, over the past few decades, theoretical and therapeutic developments have reflected the significant in-

fluence of this pessimistic and predetermined view. It was only after the introduction of various organic therapies, in the period from 1917 to 1937 (e.g., “malaria therapy,” by Wagner Jauregg in 1917; and insulin coma treatments by Sakel, cardiazol shock treatments by von Meduna, electric shock by Cerletti and Bini, and psychosurgery by Moniz, all between 1935 and 1937), that the prognosis for psychosis was viewed with greater optimism. Less known, but also significant, is the method of psychological and social reintegration used extensively in Russia, based on Pavlov’s studies of conditioned reflexes.

Relationship between constitution and personality. One other trend in psychiatric thought which emerged during the period merits brief discussion. From earliest times, man has attempted to correlate constitution, i.e., the intrinsic physical endowment, with personality type, temperament, and emotional disorder. Kallmann’s summary of the various schools of constitutional typology is reproduced in Table I. In psychiatry, the classifications of Kretschmer and Sheldon in this regard are considered most noteworthy. Kretschmer correlated the short, stocky, round pyknic habitus with extroversion, cyclothymic (cycloid) and manic-depressive psychosis; the thin asthenic leptosomic constitution with introversion, schizoid tendencies, and schizophrenia; and the abnormally proportioned dysplastic habitus with endocrine and pituitary disorders. (Many workers consider his muscular, well proportioned athletic habitus a variation of the asthenic constitution.) According to Sheldon, who applied the methodology of anthropometrics, the endomorph is temperamentally viscerotonic (sociable, relaxed, enjoys eating), the ectomorph is temperamentally cerebrotonic (antisocial, hypersensitive, secretive), and the mesomorph is somatotonie (energetic, competitive, and action-oriented).

Origins and Development of Dynamic Psychiatry: Psychoanalysis and Recent Trends in Psychiatry

The psychiatric events described refer, for the most part, to psychotic, or at least grossly disturbed, patients. In fact, even those workers who did attempt to describe and treat neurotic symptoms (like Mesmer and his followers) were largely unaware of their true origins, i.e., in the unconscious.

Nineteenth century concepts of the unconscious. Interest in the unconscious, which may be attributed primarily to the romantic movement, was evident throughout the 19th century and found expression in the five main currents of thought which were preeminent during that period.

Metaphysical concepts. The unconscious was equated with “will” by the philosophers Schelling, Schopenhauer, and von Hartmann. Carus in *Psyche* (1846) described an “absolute unconscious” and stated that “the key to the knowledge of the nature of the conscious life of the soul lies in the realm of the unconscious.”

TABLE I
Schools of Constitutional Typology^a

Nationality of School	Name of Main Investigator	Name of Constitutional Types			
		Type I	Type II	Type III	Type IV
Greek	Hippocrates	Apoplecticus	Phthisicus		
Roman	Galen	Sanguine	Melancholic	Phlegmatic	Choleric
French	Rostan	Digestive	Respiratory-cerebral	Muscular	
Italian	De Giovanni Viola	Megalosplanchnic Brachymorphic	Microsplanchnic Dolichomorphic	Normosplanchnic Eumorphic	
German	Gall-Beneke Kretschmer	Hyperplastic Pyknic	Hypoplastic Asthenic	Athletic	Dysplastic
Anglo-American	Stockard Rees-Eysenck Sheldon	Lateral Eurymorphic Endomorphic (viscerotonic)	Linear Leptomorphic Ectomorphic (cerebrotonic)	Mesomorphic Mesomorphic (somatotonic)	Dysplastic

^a Adapted from Kallmann, F. J. *Heredity in Health and Mental Disorder*, p. 56. W. W. Norton, New York, 1953.

Biological concepts. These included the "physiological unconscious" of von Hartmann, which was followed later by the "mnene" of Semon and the "psychoid" of Dreisch and Bleuler.

Concepts based on depth psychology. These refer to concepts of the unconscious which were expressed by the mystics, the mesmerists, and the parapsychologists, such as von Schubert who, in his work on dreams (1837), focused on the creative activity and symbolism of the unconscious, anticipating Freudian and, to an even greater extent, Jungian views.

Prescientific concepts. Within this category of concepts of the unconscious, one would include the forgotten memories and the subliminal perceptions of Leibnitz, Herbart, and Fechner. Herbart is particularly important for his emphasis on "unconscious representations" as the background for the conscious, which strongly influenced German psychology; Fechner was significant for his attempt to express the relationship between mind and body in mathematical form.

The concept of the dynamic unconscious. Finally, the concept of the dynamic unconscious was developed as a concomitant of hypnosis by a number of physicians of the French school. For purposes of this presentation, only this last concept of the unconscious is of interest here.

The scientific study of hypnosis. Jean Martin Charcot (1825-1893), a brilliant neurologist, described hysteria in 1870, and, in the following decade, he demonstrated the cure of such phenomena through hypnosis, which he divided into three successive stages, i.e., lethargy, catalepsy, and somnambulism. Because of Charcot's prestige at the Salpêtrière, hypnosis soon acquired wide popularity (and an equal amount of opposition from the medical profession). As opposed

to Charcot's thesis that only hysterical subjects could be hypnotized, two physicians, A. A. Liébeault (1823-1904) and Hippolyte Bernheim (1837-1919), of the School of Nancy, stressed that anybody who could be influenced by suggestion could be hypnotized. After a bitter controversy and in spite of the prestige carried by Charcot, eventually, the School of Nancy proved to be right. The last great representative of the French school was Pierre Janet (1859-1947), who was known for his concept of "psychological automatism" and for his interest in cases of simultaneous psychological existences (i.e., so-called multiple personalities, also studied by F. Myers in England and Morton Prince in this country), as well as for his attribution of neuroses to "psychic weakness."

The development of psychoanalysis. Psychoanalysis and the movements it gave rise to are discussed extensively elsewhere in this book. Therefore, this discussion will be limited to consideration of its special historical significance. Sigmund Freud (1856-1939), a brilliant neurologist and a tenacious researcher, after spending a few months with Charcot in 1885-1886, applied the "cathartic method" of hypnosis, which he had learned from Josef Breuer (1842-1925), in an attempt to relieve the neurotic symptoms of his patients. Later, he substituted for this method the technique of free association, and especially of the interpretation of dreams (the symbolism of which he described in detail in his famous book in 1900, which was based largely on his own self-analysis stemming from his relationship with Fliess). Freud also focused on the patient's resistance to treatment and his repression of significant life events. When he became more aware of the erotic nature played by the patient-therapist relationship and of the importance of

early sexual traumata in the genesis of neuroses, Freud formulated his theory of the development of sexuality. In the succeeding period, which was dedicated to the investigation of techniques of psychotherapy, Freud described in detail transference and counter-transference phenomena in the light of the libido theory, which became central to psychoanalysis. Concomitantly, the importance of didactic analysis was recognized in the training of the psychoanalyst, and the psychoanalytic technique began to acquire the structure which is maintained to this day by those who ascribe to classic Freudian theory. Later, Freud established a more plastic view of anxiety and resistance, in terms of their role in treatment; he emphasized the ego and mechanisms of defense, as well as the importance of the death instinct, and warned against too much optimism with regard to the therapeutic benefits to be derived from psychoanalysis.

From an historical perspective, undoubtedly Freud's work has the characteristics and originality of genius. Nevertheless, it should be recognized that some of his basic concepts can be followed throughout the development of medical and cultural history. The value of catharsis was recognized in ancient Greek culture. Symptoms were considered to represent a compromise between opposing forces (unconscious, sexual, life, and death) during the romantic movement and in early 19th century medicine. The unconscious was considered to play an essential role as conducive to self-knowledge by the French moralists of the 18th century and the philosophers and biologists of the 19th century. The interpretation of dreams was part of ancient tradition and was essential to the technique of incubation. Descriptions of the gradual unfolding of the sexual instinct and the developmental nature of neuroses may be found in the evolutionary concepts of Goethe, Darwin, and others. The teleological, sexual and self-preservation aims of the instincts were fundamental to Plato's basic concept of the immutability of things and their mythical return to an earlier state. Freud's concept of regression was stated earlier by Hughlings Jackson as part of his neurological concept of dissolution. The scientific character of psychoanalytic technique and its concept of behavior as predetermined are evident in the deterministic and experimental frame of reference of 19th century medicine as well. And, finally, Freud's belief that the cure depended on the insight gained by the patient was in the Platonic and orphic tradition, i.e., once man was purged of his prejudices, knowledge would replace ignorance, and "logos," thought, would prevail.

As might be expected, Freud's ideas were strongly opposed. However, the founding of several journals devoted to psychoanalysis and of the International Psycho-Analytic Association at the beginning of the century facilitated their wide dissemination, and they aroused great interest in many scientists who recognized their originality—and their validity.

Other significant forerunners of contemporary

psychiatry. Among Freud's early sympathizers Carl Gustav Jung (1876–1961) was particularly significant for the development of psychiatry. From his initial research (in 1906) on word associations and on the psychology of dementia praecox (as a result of which he demonstrated the fruitfulness of the psychoanalytic treatment of psychosis), he turned increasingly to the study of symbols in mythology and dream material. After his final break with Freud in 1913, Jung developed his concepts of the collective unconscious, of archetypes, of individuation (the emergence of the archetypal image of the self), and of the two psychological types, introvert and extrovert. Primarily because of the more speculative character of his later writings, on alchemy and religion, Jung has remained somewhat esoteric to many, and the influence of his school of analytical psychology has been limited, except perhaps in England and Switzerland.

The individual psychology of Alfred Adler (1870–1937) must also be considered of only limited influence in current psychiatric practice. Adler's early concepts of organic inferiority (1907) and nervous character (1912) progressively evolved into an increasing preoccupation with educational, social, and political issues. Historically, he is remembered in particular for his influence on child psychiatry, and, more recently, on Frankl's logotherapy.

Of Freud's other collaborators and disciples, some of whom subsequently separated from the psychoanalytic movement, mention should be made of Wilhelm Reich, whose studies of character analysis constituted a valuable contribution to the body of psychoanalytic theory; of Karl Abraham, a loyal and gifted disciple, who emphasized the importance of the preoedipal stage of development for later psychological functioning; of Wilhelm Stekel, who attempted to limit dream analysis to its manifest content. Finally, Otto Rank, the first lay analyst, elaborated on Freud's concept of the trauma of birth and attempted to shorten psychoanalytic treatment. Rank was also particularly interested in the application of psychoanalysis to mythology and literature.

In the English-speaking countries, psychoanalysis was introduced in the United States by W. A. White, E. S. Jelliffe, and A. A. Brill; in England and Canada, by Ernest Jones, who was to write the most important biography of Freud (although it is not immune from bias).

In Switzerland, Eugen Bleuler (1857–1939) and Hermann Rorschach (1884–1922) progressed along independent lines, although both were influenced by psychoanalysis. Bleuler is especially known for his comprehensive study of schizophrenia (a term he coined) published in 1911, in which he described the characteristic symptomatology of this disease. Rorschach is famous for the psychodiagnostic test he developed in 1920 which paved the way for subsequent elaboration of the so-called projective techniques.

Psychodiagnostic testing skills have since become

TABLE II
Schools of Academic Psychology (1870-1930)

School of Psychological Thought	Workers	Specific Emphasis
Structuralism	Wundt, Titchener	The study of conscious experience through introspective experimentation. Elementary psychological states, such as sensations, images, and feelings, which make up consciousness are observed and analyzed.
Functionalism	Titchener, Dewey, Angell	Like structuralism, functionalism emphasizes the study of consciousness, but in relation to environmental adaptation, through application to education (educational psychology) and people (clinical psychology).
Associationism	During the 17th century, philosophers like Hobbes, Berkeley, Locke, Brown, Hartley, Mills and Bain. In the early 19th century, Herbart. From 1885 on, psychologists, e.g., Ebbinghaus, Pavlov, Thorndike, Skinner.	The study of learning and memory, as exemplified by Thorndike's law of effect, Pavlov's law of reinforcement, and, finally, Skinner's study of learning in animals and humans, through application of the "Skinner box."
Behaviorism	Watson, Meyer, Weiss, Hunter, Lashley, Tolman, Hull, Skinner	The objective study of human and animal behavior. "Mental" concepts, such as sensation and emotion, are replaced by concepts of stimulus, response, learning, habit, and receptor and effector function. Even the study of consciousness is avoided.
Gestalt psychology	Wertheimer, Koffka, Köhler, Lewin	The total perceptual configuration and the interrelation of its parts are studied. Total experience or behavior is considered to represent more than the sum of its parts. Perception and memory are studied through introspection and observation.
Purposive or homeic psychology	McDougall	The study of goal-seeking behavior. Emphasizes striving and foresight. Human propensities (instincts) comprise the <i>ultimate</i> , primary motivation for behavior. Observations on social behavior stimulated the field of social psychology.
Organismic psychology	Coghill, Kurt Goldstein, Kantor	The holistic, biological study of the individual.
Personalistic psychology	Calkins, Stern	The holistic, social study of the individual.

part of the psychologist's armamentarium. However, on another level, brief mention should also be made of the many schools of academic psychology, e.g., structuralism, functionalism, associationism, behaviorism, which developed in the period from 1870 through 1930. The orientation of each of these schools and its chief proponents are summarized in Table II.

To return to psychiatrists of Swiss origin, also of Swiss background was Adolf Meyer (1866-1950), the founder of psychobiology, a concept which attempted to present an integrated biological and social view of the personality, in the light of which mental disturbances were conceived of as reactions. Meyer's influence on American psychiatry, which is outlined in detail elsewhere in this volume, has been tremendous, and his concept of reactions has been accepted by the American Psychiatric Association in its official classification of mental diseases.

Following the arrival in this country of many outstanding psychoanalysts from Europe in the late 1930's as a result of the rise of Nazism, psychoanalysis became widely accepted in this country, and a number of training institutes were founded in various cities. Subdisciplines, such as child psychiatry and psychosomatic medicine, became increasingly important, and psychotherapy, based on classic Freudian psycho-

analytic concepts or in modified form, became the treatment of choice for most neurotic patients. The impact of World War II served to underscore the need for a broad treatment program for mental disorders. In the United States such programs were initiated by the Veterans Administration, and eventually such legislation as the Mental Health Act of 1948 was produced. The so-called neo-Freudian schools of Harry Stack Sullivan, Erich Fromm, and others may be viewed as attempts to apply certain classic psychoanalytic concepts to today's urgent social problems (alienation, lack of individuality, urbanization, automation, poverty, and the search for values), and this trend has been further stimulated by the report published in 1960 by the Joint Commission on Mental Health and Mental Illness, entitled *Action for Mental Health*.

With the renewed interest in the biological aspects of psychiatry, following the introduction of the "psychotranquilizers" in the early 1950's, psychiatry now appears to be entering a new historical phase. It is hoped that in future decades the various biological, individual, and social trends which have characterized the developments to date will no longer be opposed to each other but, rather, may achieve successful integration and thereby ensure the further progress of this discipline.

Suggested Cross References

In this chapter the history of psychiatry was discussed in a general manner. For information regarding the history of special areas of interest such as child and forensic psychiatry, and of special disorders such as schizophrenia and mental retardation, see the chapters and sections under these respective subjects.

BASIC BEHAVIORAL SCIENCES

Human behavior, the main concern of psychiatry, is an exceedingly complex process which reflects the interaction of many divergent variables. In fact, the specific determinants of normal and abnormal human behavior are not yet fully understood; during the past decade our concepts and theories of psychic functioning have undergone constant modification to accommodate the rapid accumulation of data derived from the behavioral sciences. Concurrently, it has become increasingly apparent that behavioral determinants operate on several levels and must be considered within a sociocultural and psychological, as well as a physiological frame of reference.

If the psychiatrist is to transcend the role of clinical technician, he must acquire some insight into the nature of these basic determinants of behavior. Admittedly, much of the data derived from the basic behavioral sciences has not yet been effectively translated into psychiatric knowledge. Nevertheless, these data form the cornerstone of current research in psychiatry, which, in turn, will determine the future progress of this discipline. Concomitantly, an understanding of the determinants of normal and abnormal behavior is a prerequisite for clinical competence in the practice of psychiatry and for the effective implementation of the principles of community psychiatry.

For example, basic concepts derived from psychopharmacology, neuroanatomy, and neurophysiology provide the rationale for the application of psychoactive drug therapy. In addition, the use of this therapeutic modality requires some knowledge on the part of the clinician of the effects of a specific drug on such psychological variables as motivation, affect, thought processes, and perception, in specific psychopathological states.

Effective planning for community health services and social action for the prevention of mental illness

depends, in large measure, on the psychiatrist's awareness of the social and cultural determinants of behavior and his appreciation of the significance of such factors.

Finally, if they are to be meaningful, research projects, such as those designed to investigate the etiology of psychiatric disorder, for example, require an awareness and understanding on the part of the research worker of the multiple and varied factors which are believed to contribute to mental illness. These would include affective and cognitive experiences in early childhood, the biochemical constituents of the brain, and the social and family environment to which the patient was exposed in the past and in which he functions at present.

The sections included in this area on the basic behavioral sciences deal with some of the psychological, sociocultural, and physiological concepts which are fundamental for the understanding of human behavior and psychiatry. The general plan of organization for each section is to present the basic concepts, semantics, and methodology of the discipline. In addition, data of importance to psychiatry that derive from the field are reviewed. When feasible, this material is then discussed in terms of its direct relevance to pathological behavioral phenomena encountered in clinical practice.

To illustrate, the sections on *perception* and *cognition* define the mechanisms of these functions as normal phenomena. In addition, these sections discuss the perceptual and cognitive disorders characteristic of such psychiatric disorders as schizophrenia and mental deficiency and describe the application of concepts and methods deriving from the study of perceptual and cognitive functions to the clinical use of psychological test procedures.

Ethology is discussed in terms of the relevance of

data about animal behavior to the understanding of human behavior, especially to developmental theories which are intrinsic to the study of child psychiatry. In addition, the possible application to psychiatry of the methodological procedures employed in ethology, as well as the potential value of such application, is explored.

Basic concepts of *psychopharmacology* and *neurochemistry* are discussed with specific reference to the clinical use of psychopharmacological agents. These sections also present the biochemical data which have been accumulated to date relevant to the understanding of the behavioral manifestations of the organic brain disorders and psychotic states.

The section on *learning theory* is concerned, first, with the manner in which pathological behavior is ac-

quired, and, secondly, with the application of the principles of learning theory to the treatment of such psychopathology.

Similarly, the sections on *anthropology* and *sociology* focus on the application of the data derived from these disciplines to milieu therapy and community psychiatry, and on the value of the methodological procedures unique to these fields for the study of the etiology of mental illness.

Thus, despite the fact that the relevance of this material to the complexities of human behavior and clinical psychiatry is not precise at the present time, there is compelling reason to believe that findings in these areas will eventually be translated into knowledge which will facilitate theoretic and therapeutic progress in psychiatry.

Chapter 2

Basic Biological Sciences

2.1 GENETICS AND PSYCHIATRY

JOHN D. RAINER, M.D.

Until the early 1930's, development in the fields of genetics and psychiatry followed separate paths. In the behavioral sciences, heredity and environmental factors were considered as separate, if not distinctly different, entities. Many psychiatrists were deeply concerned with the ancient dichotomy between nature and nurture and between mind and matter; as a result, they tended to separate the biological and the psychological disciplines.

For many years, the behavioral sciences were dominated by viewpoints similar to that expressed by J. B. Watson, who believed that one could produce any kind of human being if allowed to manipulate that individual's environment from an early age. Meanwhile, American psychiatry was under the constructive influence of Adolf Meyer, who considered mental disorder largely as a maladaptation in the face of environmental stresses. A number of family studies of the major psychoses were reported by Rosanoff, Pollock, Malzberg, and others, and biologists such as Raymond Pearl worked in the tradition of Galton and Pearson. But in the transplantation of psychoanalysis from Europe to the United States in the middle 1930's and its flourishing during and immediately after World War II, the attention that Freud and Ernest Jones had given to inborn differences was largely forgotten. Freudian psychoanalysis, particularly some of its offshoots in the United States, combined therapeutic zeal with exclusive attention to psychogenesis.

A few of that generation of psychoanalysts showed exceptions to this trend. Among these was Rado, who conceived of a unitary scheme of psychology with psychodynamics resting on the solid bases of genetics and physiology. The publication of Kallmann's Berlin family study and subsequently of his New York twin investigation in schizophrenia changed American psychiatry profoundly, by calling attention to the importance of genetics in many psychiatric conditions.

The area of Kallmann's work included schizophrenia, manic-depressive psychoses, homosexuality, mental deficiency, aging and longevity, tuberculosis, early deafness, and genetic counseling.

In the last decade, a more general shift in American psychiatry could be seen. Major advances in cytological and biochemical genetics not only captured the imagination of many psychiatrists but pointed to an understanding of the possible mechanisms of genetic influence. Experimental psychology was studying individual differences in various species from drosophila to dogs. The theory of interaction of genetic and ecological forces in human development became predominant, and the problems of population growth began to draw attention to important aspects of population genetics and human evolution. At the same time, on the basis of clinical observations, psychiatrists were beginning to be aware of the importance of family patterns, individual differences, and metabolic and pharmacological distinctions.

In considering the relation of genetics to psychiatry, we can conceive a series of organization levels: the molecular and cellular, the biochemical and neurophysiological, the psychodynamic, the demographic, and the social. In each of these areas, the continuous interaction of the organism with its surrounding forces determines its status at any given time; that is, there is an interplay of all the factors affecting human development—whether genetic, chromosomal, cytoplasmic, biochemical, embryological, metabolic, experiential, or social. The goal of psychiatric genetics as a science may be considered, in the broadest sense, to be the clarification of the mechanisms of cause, of effect, and of interaction not only in psychiatric disease but in normal behavior.

Classical Genetics

Gregor Mendel's report on his garden pea experiments in 1865 paved the way for the modern theory of genetics. His observations led to the postulation that a genetic substance, which was not blended but rather remained intact during an individual's life, was transmitted in the form of stable units to his offspring. His ideas led to the description of populations in mathematical terms. The development of genetics later merged with that of the theory of evolution. Originally, Mendel's conclusions were statistical in nature. Counting the variations that he found in the progeny of certain matings, he

inferred that each trait existed as if determined by paired particles (later called genes) in the germ plasma. From this inference, a number of general principles of inheritance were derived.

In classical genetics it is assumed that single genetic traits are determined by paired genes, one of which is derived from the male germ cell and the other from the female germ cell. One may speak of the total genetic constitution of the individual as his genotype and of his appearance at any given time as his phenotype. A person receiving a given gene from both parents is called a homozygote for that particular gene, and under proper environmental conditions he will be certain to show its characteristics. If an individual receives the given gene from one parent and a different gene at the corresponding locus from the other parent, he is known as heterozygote. In some cases, the heterozygote will display traits intermediate between those represented by homozygotes; in other cases he will display the trait as a homozygote does; in this instance, the trait is known as dominant. In still other cases, he will not display the trait; in this instance, the trait is known as recessive; that is, it is expressed only if both genes are present.

Mutant genes. If a single mutant gene can express itself against the genetic background of many other factors, its phenotype effect in most cases will tend to be pathological.

Simple dominant traits tend to be rare and incompletely expressed. When they appear, they are transmitted in the direct line of descent by inheritance from one parent. They may be easily studied in pedigrees, and they appear in approximately 50 per cent of the offspring of one affected parent (see Figure 1, for example). Matings between two affected persons are rare, and a negligible role is played by consanguineous marriages.

FIGURE 1. A pedigree of Huntington's chorea, illustrating dominant inheritance. (From the Department of Medical Genetics, New York State Psychiatric Institute.)

FIGURE 2. Diagram of theoretical expectations in simple recessive inheritance, e.g., phenylketonuria. (From the Department of Medical Genetics, New York State Psychiatric Institute.)

In simple recessive traits, inheritance from both parents is necessary. The parents themselves are frequently unaffected, since they are usually heterozygotes. If two heterozygotes mate, each child has a 25 per cent chance of being a homozygote and, therefore, an affected individual (see Figure 2, for example). In relatively rare disorders, consanguineous marriages are apt to increase the chances of such affected offspring. Transmission of a simple recessive trait is usually along collateral rather than direct lines of descent.

Not all mutant genes in man conform to a simple mode of inheritance. A gene does not produce a given trait directly. It merely begins a long series of reactions that may be modified by environmental factors, both prenatal and postnatal, as well as by the action of other genes. Gene effects, therefore, may vary from complete expression to no apparent expression at all. There are genes that are neither completely dominant nor completely recessive but somewhere in between. Since recessive genes may express themselves mildly in heterozygotes, methods for their detection are of great importance in the practical application of genetic counseling.

Multiple genes. In addition to single factor types of inheritance, certain traits are determined by the interaction of several or many genes. This type of inheritance is called multifactorial, with contributions made in a cumulative manner by a number of genes that by themselves produce only minor effects. Such genes are neither dominant nor recessive but are intermediate in their effect. Modifier genes may change the expression of a major gene, and suppressor genes may limit its effect entirely. For many traits such as height, weight, intelligence, and perhaps personality variations that show small gradations within the range of normalcy, multifactorial inheritance may be at work.

Human Cytogenetics

During the 3 decades in which Mendel's findings remained unnoticed, the discovery of the chromosomes in the cell nucleus took place. These specially staining threadlike bodies were observed to divide in the process of cell division and to be distributed as exact duplicates. But in the formation of germ cells, each cell received only half of the chromosomes in the parental cells. These facts turned out to be consistent with the statistical findings of Mendel, and thus it became possible to combine data derived from breeding experiments with the microscopic study of cells and chromosomes. For instance, if a gene is situated on one of the 22 pairs of autosomes, the type of inheritance is called autosomal and the distribution of the trait between the sexes is equal. But if a gene is transmitted on the sex chromosomes, the inheritance is called sex-linked, and the distribution of the trait between the sexes is unequal. In recessive X-borne conditions, for example, males are more frequently affected than females because males have only one X chromosome whereas females have two.

Nevertheless, the study of chromosomes in the human was long neglected. There was no agreement on such simple matters as the number of chromosomes and the mechanism by which sex was determined chromosomally. Most textbooks stated that the total number of chromosomes in each normal human cell is 48, a figure found to be incorrect in recent years. The number is now established as being 46. And although it was known that females had two X chromosomes and males one X and one Y, it had been er-

roneously thought that the Y chromosome was inactive, sex being determined by the number of X chromosomes. Until recently, methodology was not advanced to the point where clinical abnormalities could be correlated with chromosomal aberrations.

Sex chromatin and nuclear sex determination. In 1949, the first recent major discovery in human cytogenetics was made in Canada by Barr and Bertram, who uncovered an important difference between male and female cells while studying neurons of the cat. The investigators found a dark staining mass of chromatin in the nuclei of many cells. They soon made the crucial observation that it was the female cat that had this chromatin substance. Before long, this difference was shown to exist in other mammals, including man.

The determination of sex chromatin in the human is not a difficult procedure. It is done most easily by examining a smear made of buccal mucosal cells. The cells are scraped from the inside of the mouth, put on specially prepared slides, fixed and stained, and from one to two hundred cells are counted. The mass is seen plastered against the nuclear membrane. From 30 to 60 per cent of the cells of the normal woman show this dark staining mass, which is now referred to as sex chromatin, or, after its discoverer, a Barr body (see Figure 3). The origin of the sex chromatin body is still not completely clear. Originally, it was believed that it consisted of parts of both X chromosomes. This theory was discarded in favor of one derived from the so-called Lyon hypothesis, which states that in the early embryonic development of the female, one X chromosome in each cell is inactivated. Accordingly, the Barr body is thought to represent all or part of this inactivated chromosome.

In 1954, a second difference between male and female cells was discovered. A drumstick-like appendage attached to one of the lobes of the nucleus of polymorphonuclear leukocytes was consistently noted in over 2 per cent of cells in females and in an insignificantly small number of cells in males.

Turner's syndrome. The technique of nuclear sexing soon led to the discovery of chromatin abnormalities in certain human sexual anomalies. In one of these, Turner's syndrome, cells were found to lack the Barr body. Girls with this syndrome are short and have infantile genitals, and their gonads are reduced to connective tissue streaks. There are other defects, such as webbed neck, short fingers, and shield chest. This anomaly appears in about one in 3,000 newborn females. Some patients with Turner's syndrome show intellectual impairment, but the condition is not usually associated with severe mental deficiency. Initially, these individuals were called "chromosomal males" because they lacked the chromatin patch.

Klinefelter's syndrome. Another syndrome studied on the basis of the presence or absence of sex chromatin was Klinefelter's syndrome. This condition occurs in males and includes small, atrophic testes,

usually with sterility; notable gynecomastia; and increased excretion of gonadotrophin. It appears in one in 350 male births, but accounts for 1 per cent of mentally retarded male patients in institutions. Klinefelter's syndrome was found to be associated with the presence of a Barr body, usually absent in the male, and for a time these patients were called "chromosomal females."

Development of chromosome technique. In 1956 improved methods of visualizing and counting human chromosomes promised to clarify many of these cytogenetic problems. Since chromosomes become visible and distinguishable only at the metaphase stage of a dividing nucleus, it was necessary to obtain cells in the process of division. Early investigations had been done with testicular tissue, and individual cells with visible and distinguishable chromosomes had been observed. However, these chromosomes clumped together and overlapped, rendering attempted counts inaccurate.

The problem of obtaining many cells in a dividing stage was dealt with by the use of tissue culture methods whereby cells from skin biopsy or from blood could grow and divide in vitro in tissue culture media. In order to arrest the cells at the metaphase stage, where the chromosomes may be distinguished, colchicine or other mitotic poisons were added to the culture medium shortly before the cells were harvested. In order to avoid clumping and overlapping of the chromosomes, the cells were suspended in a hypotonic solution in the stage before staining. This hypotonic solution swelled the nucleus and scattered the chromosomes over a larger area to make them discretely visible. Finally, the cells were centrifuged, spread on slides, dried, and stained.

Currently, most cultures are prepared with lymphocytes. They are stimulated to turn into large lymphocytes and to divide by the addition of a foreign antigen such as phytohaemagglutinin, a plant substance. The entire process of cell growth and harvesting takes about 72 hours.

Normal human karyotype. Tjio and Levan, in 1956, found by tissue culture methods that the number of chromosomes in

FIGURE 3. Sex chromatin in buccal mucosal cells (left, chromatin-positive; right, chromatin-negative). (From Cytogenetics Laboratory, Department of Medical Genetics, New York State Psychiatric Institute.)

man is 46. It soon became possible, by enlarging the photograph of the microscopic field and cutting each chromosome out, to arrange the chromosomes in descending order of size, thus producing a visual representation of the chromosome complement or karyotype. Since each chromosome is photographed at the stage in which it duplicates itself, the chromosomes have the appearance of a letter "X" or an inverted letter "V," each chromosome and its new partner remaining connected at one point, called the centromere. The chromosomes are distinguishable within size groups by the position of this centromere, which may be either median or toward one end. The median or submedian chromosomes are known as metacentric; the subterminal or terminal ones are acrocentric.

In 1960 the numbering system was standardized, the chromosomes being divided into seven groups (see Figure 4). Group A, made up of chromosomes 1 through 3, consists of large chromosomes with approximately median centromeres; these chromosomes may be easily distinguished from one another by their size and the location of the centromere. Group B, chromosomes 4 and 5, consists of large chromosomes with submedian centromeres; these chromosomes are more difficult to distinguish from one another. Group C, chromosomes 6 through 12, consists of medium-sized chromosomes with submedian centromeres; they are not easily distinguishable one from one another morphologically; the X chromosome resembles the larger chromosomes in this group. Group D, chromosomes 13 through 15, consists of medium-sized chromosomes with centromeres which are nearly terminal in location. Group E, chromosomes 16 through 18, contains rather short chromosomes with approximately median or submedian centromeres; chromosome 16 is easily distinguishable because its centromere is median, and it looks like a small letter "x." Group F, chromosomes 19 and 20, contains short chromosomes

with approximately median centromeres. Group G, chromosomes 21 and 22, is made up of very short acrocentric chromosomes; the Y chromosome is similar to these in size.

Recent techniques of autoradiography, in which cells are grown in a labeled medium and the uptake of radioactive substance at various stages in chromosome replication is measured and visualized, indicate that in the various groups certain chromosomes replicate later than others. This characteristic serves to distinguish chromosomes that are difficult to recognize by appearance alone.

Chromosomal aberrations

Nondisjunction. The 3 years following the correct description of the human karyotype were fruitful ones in cytogenetics. Even before the numbering system was standardized, a number of aberrations were described. One group of aberrations was marked by the presence of an extra chromosome, so that there were 47 rather than 46 chromosomes in the karyotype. The extra chromosome represented the presence of 3 rather than 2 of a given chromosome. Such an anomaly arises through a process of nondisjunction, usually in the formation of the sperm or the egg cell. In the splitting of the cell, 1 chromosome of each pair ordinarily goes to each of the daughter cells. If the two chromosomes of a given pair remain joined and migrate together to one of the daughter cells, that cell will have an extra chromosome. When that daughter cell combines in fertilization with a normal gamete, a zygote or single cell stage individual will be formed with the extra chromosome.

Down's syndrome (mongolism). Three viable types of nondisjunction causing trisomic conditions

FIGURE 4. Karyotype of normal woman. (From the Cytogenetics Laboratory, Department of Medical Genetics, New York State Psychiatric Institute.)

have been described. In these conditions the autosomes, as distinguished from the X and Y or sex chromosomes, are involved, and the affected chromosomes are triple instead of double. The first type described was the trisomy of a chromosome in group G in mongolism, better termed Down's syndrome, after the man who first described it in 1866. It had been known for a long time that most cases of this syndrome occurred in children born to older mothers. At the same time, however, the concordance rate in one egg twins was close to 100 per cent. These findings foreshadowed an early germinal, possibly chromosomal, defect as the responsible agent. In 1959, Lejeune and others demonstrated by tissue culture methods the presence of an extra small acrocentric chromosome in patients with Down's syndrome. It is very likely that this condition arises by nondisjunction in the formation of the maternal ovum. The delicate balance of chromosomes is indicated by the fact that an extra one causes such widespread chemical, morphological, and psychological effects.

If the extra chromosome is lost through disjunction in the early cell divisions of the zygote, two cell lines may persist, one with 46 and one with 47 chromosomes. The individual will be known as a mosaic and may have an intermediate degree of symptomatology.

A third mechanism in mongolism was first postulated by Polani on the basis of the investigation of the chromosome complement in a mongoloid child born to a young mother. Chromosome count revealed the normal number of 46, but 1 of the chromosomes in group D turned out to be longer than normal. It was suggested that this oversized chromosome consisted of an extra G chromosome joined to the long arm of a D chromosome; in such cases there are, in effect, 3 G chromosomes. It has sometimes been found in these cases that the mother or the father has such a long D chromosome also, but the added unit is balanced by the absence of 1 of the unattached G chromosomes, leaving the individual with a total number of only 45 chromosomes. Such a parent is a carrier, and his children have approximately 1 chance out of 3 of being affected.

This interchange of chromosomal material is known as translocation. It may also occur in Down's syndrome between 2 chromosomes in the G group. The difference between trisomy and translocation is very important from a practical point of view. Most mothers who have a child with Down's syndrome have a small risk of producing a second one; the risk is no greater than for other women their age. At the highest, this risk is about 1 in 50 for mothers over 45. But if a mother is a translocation carrier, she has a risk of about 1 in 3 of having an affected child.

Other autosomal trisomies. A second autosomal trisomy syndrome is the trisomy 17-18 syndrome. Infants affected by this syndrome fail to thrive and live only a few months. Among the defects they

show are apparent mental retardation, a small mandible, low set ears, eyes wide apart, fingers flexed with a dorsal crossing or overlapping of the digits, and hypertonia. A third trisomy, of one of the chromosomes in group D, also results in failure to thrive, mental retardation with associated eye defect such as microphthalmia or anophthalmia, often cleft palate and hare lip, polydactyly, and occasionally congenital heart disease.

Deletion. In addition to nondisjunction and translocation, a third mechanism causing chromosomal anomalies is that of deletion. In this condition part of a chromosome breaks off during cell replication, and future cells have a smaller sized chromosome than usual. The *cri du chat* syndrome described by Lejeune is associated with a deletion of chromosome 5. Children displaying this syndrome fail to thrive; are mentally retarded; show microcephaly, hypertelorism, and low set ears; and emit a characteristic mewlike cry similar to that of a kitten.

Abnormalities involving sex chromosomes. Contrary to the normal patterns, certain males show the sex chromatin patch, and certain females do not. Chromatin-positive male patients with Klinefelter's syndrome, once their karyotype is determined, are found to have 47 chromosomes. They do indeed have 2 X chromosomes, but they also possess a Y chromosome. The 2 X chromosomes are sufficient to cause the appearance of the Barr body, but the Y chromosome causes them to have male gonads and essentially male genitals. Such an anomaly may be brought about by the union of an abnormal XY sperm with a normal ovum or by the union of an abnormal XX ovum with a normal Y-bearing sperm. In each case, the abnormal gamete is the result of nondisjunction. Similarly, most girls with Turner's syndrome and no Barr body are found to have a karyotype containing only 45 chromosomes; they have only 1 X chromosome, the other sex chromosome being missing. This condition is called the X0 condition, "0" referring to the absence of a chromosome that is normally present. In this case, a nondisjunction may result in a sperm cell or an ovum containing neither an X nor a Y chromosome; the union of such a deficient cell and an X-bearing gamete results in the given anomaly.

Another abnormality involving the sex chromosomes is seen in the "superfemale," who is actually sexually infantile and amenorrheic, having 47 chromosomes with 3 X chromosomes and 2 Barr bodies.

The above findings and many variations thereof establish certain important principles in human sex determination. First, the presence of a Y chromosome appears to be both necessary and sufficient for the formation of male gonads, regardless of the number of X chromosomes the individual possesses. Individuals with XXXY or XXXXY karyotypes are basically males in spite of severe anomalies. Second, the sex chromatin pattern seems to be related in a simple way

to the chromosome count: the number of Barr bodies is always one less than the number of X chromosomes.

Significance of chromosomal variations. It is too early to assess the value of chromosomal studies in unraveling the processes of human gene action. At present, such studies are valuable in the analysis of cases for genetic diagnosis and counseling. In the future, by correlating specific metabolic abnormalities with diseases involving certain chromosomes, it may be possible to further the localization of human genes and mapping of human chromosomes. A number of observations foreshadow this development. It is known, for example, that acute leukemia is frequently found in patients with Down's syndrome (trisomy G); at the same time, in patients with chronic myelogenous leukemia, one of the chromosomes in group G is abnormally small. It is likely, therefore, that some of the lesions in this type of leukemia may be traceable to genes located on this chromosome.

Chromosomal findings in psychiatric syndromes other than the mental deficiencies and sexual anomalies already described have thus far not been striking. A suggestive, but not statistically significant, correlation between sex chromosome anomalies and schizophrenia in large populations has been described, and many of the mental deficiency states associated with abnormal karyotypes evince psychotic types of behavior. It may someday be possible to localize some of the genetic mechanisms in human behavior. This has already been done in the fruit fly; strains of flies have been bred to travel either from or toward the light or away from or toward gravity. These strains have then been analyzed by crossbreeding experiments involving known markers to determine the contribution of the various chromosomes to their behavior.

Biochemistry of Genetic Substance

Structure of DNA. In the biochemical laboratory, there have been outstanding advances in elucidating the nature of the genetic substance itself. By 1952, chemists had determined that the genetic material transferred from generation to generation and carrying genetic information is not protein, as had long been thought, but deoxyribonucleic acid (DNA). It was found possible to transform a bacterium of one type to another by injecting it into an animal together with pure DNA of the second type. It was also found that in certain viruses the effective part was DNA. Chromosomes are composed of DNA and protein, but DNA appeared to be the primary genetic material.

In 1953, the structure of this molecule was proposed by Watson and Crick. It had been known that DNA contains four nitrogenous bases—two purines (adenine and guanine) and two pyrimidines (cytosine and thymine)—that the amount of adenine equals the amount of thymine, and that the amount of guanine equals the amount of cytosine. Watson and Crick suggested that DNA consists of two chains of five-carbon sugars held together by phosphate bonds and that each of these chains is twisted in the form of a helix. From each sugar on one chain to a corresponding sugar on the other, there is a linkage between either adenine on one chain and thymine on the other or guanine on one and cytosine on the other, the linkage held together by hydrogen bonds. A DNA molecule may consist of thousands of such nucleotide linkages.

Functions of DNA. On the basis of this DNA structure, it is possible to explain the two main functions of the genetic material: (1) its ability to duplicate itself exactly and (2) its ability to transfer information to the cytoplasm of the cell and bring about the synthesis of unique enzymes or other proteins.

Replication. If the two chains forming the double helix separate, breaking the linkages between the nucleotides, each half may then extract, from the surrounding nutrient material, substances with which to reconstruct a sister chain. In this process, the sequence of nucleotides on each sister chain must be complementary to that on the original half-chain. One is left with two double helical chains, each of which is identical to the original.

Protein manufacture. The process of protein manufacture is more complex and involves additional molecules. Basically, it is believed that a sequence of 3 nucleotide linkages is associated with the final production of a given amino acid. As there are 21 amino acids and 64 possible linkages of 3 nucleotides, there are more than enough different combinations, and some redundancy is probable. The process begins as the message on a portion of the DNA, is transferred to a single stranded molecule known as ribonucleic acid (RNA), which then moves out into the cytoplasm of the cell. The sequence of nucleotides in the RNA is the same as in the DNA except that thymine is replaced by uracil. This RNA attaches itself to structures in the cytoplasm of the cell known as ribosomes.

Meanwhile, the amino acids derived from the diet and present in the cytoplasm attach themselves to a type of genetic molecule called transfer-RNA, a long chain bent like a hairpin and twisted into a helix. A given molecule of transfer-RNA is able to attach itself at its free end to one—and only one—of the amino acids. At the bend of the hairpin, a sequence of three nucleotides searches for its unique complementary sequence on the messenger-RNA and attaches itself thereto. In this manner, the messenger-RNA serves as a template that specifies how a sequence of amino acids, each accompanied by its appropriate transfer-RNA molecule, will line up. These amino acids form bonds, one with the other; the transfer-RNA molecules separate off, and the resulting chain of amino acids or polypeptide remains. These polypeptides form proteins, which may be enzymes or structural proteins such as hemoglobin.

Mutations. Gene mutations represent changes in the genetic instruction so that new cells produce different substances than do the cells that preceded the mutation. If these mutations take place in germ cells, they may produce a change in the genetic information contained in the zygote and, depending on the locus of the mutation, a resultant particular enzyme deficiency or disease.

In the framework of the modern theory of gene action, a mutation may be considered as a change in the sequence of nucleotides in the DNA. Such changes may take place through a mistake in the replication process at the time the cell divides, possibly through the action of certain chemical compounds, or as a result of high energy radiation. The changes may consist of the addition of an extra nucleotide pair, the subtraction of a nucleotide, the substitution of one nucleotide for another, or various rearrangements of the nucleotide sequence. From then on, a changed message is sent via the messenger-RNA to the cytoplasm, and a different protein is produced.

Control of DNA function. One of the basic questions in this picture of gene action and protein synthesis is the problem of control or regulation. Every so-

matic cell in the body has the same 46 chromosomes, all of them descendants of those in the original one cell or zygote, but it is clear that cells differentiate and perform different functions. Not every chromosome, therefore, is transferring its total message at all times.

Various theories have been propounded to account for the control of gene action. One theory, propounded by Jacob and Monod on the basis of the study of bacteria, states that there exist both structural genes, whose message determines the production of enzymes or structural materials produced by the cell, and regulator and operator genes. The regulator and operator genes switch the structural genes on and off, depending on the presence and quantity of the substrate on which the genes act or of the product that the genes produce. Thus, a type of feedback mechanism insures a regulation of the genes by their surroundings. More complex mechanisms may play a role in higher organisms. These may represent the basic prototypes of interaction, a concept of primary importance in psychiatric genetics.

Inborn Errors of Metabolism

One of the classic writings on genetics early in this century was the series of papers by Garrod, dealing with inborn errors of metabolism. Garrod foresaw the concept of genes determining enzyme production and conceived of the idea of metabolic blocks in which the absence of a necessary enzyme caused the intermediary metabolism of a certain substance to proceed in a faulty direction. His theory also foreshadowed the one gene-one enzyme hypothesis of Beadle and Tatum.

Phenylketonuria. One example of a genetic defect in metabolism with notable effect upon the brain is phenylketonuria. This condition was described in 1934 by Fölling, who noted 10 patients, some of them siblings, who were mentally deficient and who excreted phenylpyruvic acid. Jervis discovered the single autosomal recessive inheritance of this condition, observed large amounts of phenylalanine in the blood of these patients, and pinpointed the metabolic error as the absence of the enzyme, phenylalanine hydroxylase, which ordinarily oxidizes phenylalanine to tyrosine.

The heterozygous carriers, the parents of such children, have a reduced enzyme level, which is best detected by giving a test dose of phenylalanine and observing the plasma level 1 to 4 hours later. In this tolerance test the plasma phenylalanine concentration of the heterozygotes may be twice that of normals.

Clinical characteristics. As a recessive condition, phenylketonuria will occur on the average in one child out of four if both parents are heterozygotes. There is equal distribution of the condition between the sexes. Clinically, the first manifestations of mental retardation occur at about 6 months. Most patients develop to idiot level, a few develop to imbecile level, and a small number have borderline intelligence. Other characteristics of the disorder are seizures, psy-

chotic symptoms consisting of destructive and noisy episodes and temper tantrums, skin manifestations consisting of eczema, dry or rough skin, and often blond hair and blue eyes. Patients with this disorder account for about 1 per cent of the population of institutions for mental defectives.

Case detection. Until recently, phenylketonuria was detected by the ferric chloride test, in which a 5 per cent solution of ferric chloride added to fresh urine produces an olive green color, which fades within an hour or two. This test, however, frequently does not give a positive result until the individual is 4 to 6 weeks of age, when it may be difficult to follow up a child already discharged from the hospital. Recently, a simple test for detecting elevated phenylalanine levels in the blood of newborn infants was devised by Guthrie. At present, many states require that every newborn child be tested by this technique. Prior to the use of the Guthrie test, the incidence of phenylketonuria was thought to be about 1 in 25,000. Present determinations, excluding false positive results, yield an incidence of closer to 1 in 10,000.

Management. In line with the dictum that a genetic disease represents interaction between a gene-borne deficiency and the environment, Jervis found it possible to prevent the mental deficiency that develops in the phenylketonuric by supplying an environment relatively free of phenylalanine by means of a low phenylalanine diet. Infants started on such a diet in the first few months of life may develop normally, even though the enzymatic deficiency is present. Indeed, such infants have been removed from these special diets at the age of 5 or 6 years; although the phenylalanine level in the blood subsequently rose, there was no effect on intelligence. This phenomenon represents an example of the relation of gene-borne deficiencies to time of life. A new problem is presented in the case of females who grow to adulthood and have children while their phenylalanine level is high. In these cases, placental transfer may cause brain damage in the child, even though the child is not a homozygote for phenylketonuria. It has been recommended that such women be returned to a low phenylalanine diet before pregnancy.

Drug sensitivity. There is evidence that there may be inherited differences in response to drugs. This has given rise to a discipline known as pharmacogenetics. One example of an abnormality in this area with psychiatric implications is pseudocholinesterase deficiency. Individuals with a low concentration of this enzyme in the plasma and with an atypical form of the enzyme show a prolonged reaction to the drug succinylcholine. This skeletal muscle relaxant, acting at the neuromuscular junction, is usually destroyed by pseudocholinesterase and therefore has a very short duration of action. Succinylcholine is used in anesthesiology, particularly during endoscopic procedures and reductions of fractures and dislocations. It is used in psychiatry during electroshock treatment in

order to avoid strong convulsions and muscular contractions that might cause bone fractures. In persons with atypical esterase, an excessive amount of the drug reaches the nerve end plate. Even a small test dose of the drug may cause 10 to 15 minutes of apnea in a patient with this metabolic disorder.

According to Kalow, this condition is determined by an autosomal gene. Persons homozygous for this gene have only atypical esterase; heterozygotes have mixtures of atypical and typical. Homozygotes account for about 1 person in 3,000; almost 4 per cent of the population may be heterozygotes. Determination of pseudocholinesterase activity in persons who are to receive electroconvulsive therapy and adequate provision for artificial respiration would reduce the seriousness of prolonged apneic reactions to succinylcholine.

Principles of Population Genetics and Evolution

Genetic factors determine important short and long range effects in human populations. A population may be defined as a group of individuals tending to mate among each other. Such a reproductive community will share a common gene pool, within which the relative frequencies of various genes may be specified. In a human population, other distinguishing features may be of a geographic, cultural, socioeconomic, ethnic, or psychological nature. These considerations may tend to isolate certain subpopulations within the main population. The changing stratification of such subpopulations will exert a definite effect on the genetic composition of the given population groups.

Hardy-Weinberg equilibrium. The basis for a systematic approach to population genetics is a simple formula called the Hardy-Weinberg law. This law describes an equilibrium state in an ideal population that will exist from generation to generation. It expresses, in terms of the gene frequencies, the expected values of the various genotypes if the following conditions are met: random mating, with every male individual having the same chance to mate with any female; no selective advantage or disadvantage of any one gene over the others at the same locus; and absence of mutations. In addition, the ideal Hardy-Weinberg equilibrium assumes a very large and geographically stable population.

The main importance of the law lies in the fact that it demonstrates a continuation of population variations from generation to generation rather than a trend toward increasing uniformity. If any of its conditions are not fulfilled, there is interference with the population equilibrium.

Causes of disequilibrium

Interference with random mating. A change in the relative proportion of homozygotes and heterozygotes will be brought about by any interference with random mating, such as consanguineous marriage, assortative mating, and the persistence or development of population isolates. Such practices will result in an increase

of recessive phenotypes, particularly in the case of relatively rare conditions, since there will be an increased trend for two heterozygous carriers of recessive genes to mate and produce homozygous offspring.

Genetic drift. In small populations, even with random mating, there will be chance variations in the relative frequency of genes from generation to generation. This phenomena, known as genetic drift, will lead to fluctuations of gene frequencies, despite the absence of mutation, selection, and assortative mating.

Mutation and selection. Mutations, now understood in biochemical terms as a change in the DNA molecule, may be described in terms of calculable frequencies with definite effect upon the gene pool for future generations. Mutations tend to cause changes not only in gene frequencies but also in the adaptiveness of individuals. In this process these individuals become subject to the action of selection, which may be defined as genetic advantage or disadvantage measured in terms of mean family size. If individuals of a certain genetic constitution produce an increased number of offspring, this is known as positive selection. A trend toward elimination of a trait due to a disadvantage is known as negative selection. To be sure, advantage is determined not only by the effect of individual genes determining unit characters but by general genetic aspects of fitness and adaptiveness to the environment, which may be determined by the action of many genes, in both homozygous and heterozygous form. Selection may be mediated by differences in mating, fertility, emigration, and early mortality.

Methods of Genetic Investigation

In genetic population studies various approaches have been used, some favoring the analysis of the health problems of individual families, others studying entire populations. Since Mendelian ratios express only the average expectancy of a gene-controlled trait in a representative population sample, various statistical procedures are necessary to determine the validity of inferences drawn from individual observations.

Pedigree method. Genetic data obtained from individual pedigrees or individual pairs of siblings or twins are useful in the study of rare pathological conditions that are fairly constant in their penetrance and clinical expression. Such data are not calculated to furnish conclusive proof about the operation of heredity or about the mode of inheritance involved. Since family histories are often published only if there is a concentration of affected individuals, the data are of limited value, since they are not statistically representative of the population.

Census method. Total population surveys by the census method are valuable but difficult to conduct. The populations must be sufficiently cooperative and not too large, and the traits under investigation must be relatively uncomplicated ones. Nevertheless, in certain special populations, particularly in regions of

Scandinavia, excellent psychiatric studies using this method have been produced.

Family risk studies. A very useful method of genetic investigation has been termed the contingency method of statistical prediction. The aim of this method is to compare the expectancy of a given medical condition developing among relatives of affected individuals with the expectancy in the general population. The condition in question must be well defined so that a number of independent observers may accurately diagnose persons coming into the study. And the original group of patients whose relatives are to be investigated must be either a consecutively reported series representing a complete ascertainment or a random sample thereof. If this criterion is met, members of the group may be called index cases or probands. They generally represent all admissions to a given hospital system or clinic over a given period of time or at least a properly selected sample of such a list.

Not all the relatives who are free of symptoms will necessarily remain so if they live to an older age. For the relatives, therefore, one cannot simply consider the prevalence of the condition; one must also obtain a corrected figure known as the expectancy rate. A simple means of calculating this is Weinberg's abridged method. The number of observed cases among the relatives (the numerator) is related not to the total number of relatives but to all those who have survived the period in which the disease may be certain to be manifested plus one-half the number who are still within the age limits during which the disease may be manifested (the denominator). Persons who died before the earliest manifestation age of the given disease or who are still under that age are not counted as part of the denominator. This method yields morbidity risks that approach the average expectancy of developing the given condition in persons who remain alive through its manifestation period. These expectancy rates for various groups of relatives may be compared with one another and with the expectancy rates for the general population. General population rates have been obtained in many medical conditions through careful demographic studies of whole populations of small areas or of samples of populations of larger districts.

Twin-family method. The basic principles of the contingency method have been applied to an extended approach termed the twin family method. The use of twins in genetic research was initiated by Galton and is based on the occurrence of two genetically different types of twins: those derived from one fertilized ovum and those derived from two fertilized ova. The former are always of the same sex (barring a rare sex chromosomal nondisjunction prior to the first cell division, which may result in a pair of identical twins comprising a normal male and a Turner's female); two egg twins may be either of the same sex or of opposite sexes.

In the twin-family method, data are obtained on complete sibships of twin index cases and their parents. Comparisons are made between one egg twins, two egg twins of the same sex, two egg twins of opposite sexes, full siblings, half siblings, and step siblings. This procedure provides a unique opportunity to investigate intrafamily variations with a minimum of uncontrolled variables. Comparisons can be made between one egg twins brought up and living together and two egg twins under the same conditions. It is more difficult to find one egg twins who have been raised apart and who present a particular syndrome—at least in sufficient numbers to warrant drawing conclusions from concordance rates.

Certain significant misunderstandings concerning twin studies should be noted. Carefully stated hypotheses should not be questioned simply because pairs of dissimilar one egg twins have been found. Genes actually determine a norm of reaction, the exact expression of which depends on many interactions taking place before, at, and after birth. Indeed, one egg twins, especially those with a common chorion, are subject to more disparate influence before birth than two egg pairs, as a result of circulatory variations. There are many pathways from identical genetic structures to later expression of behavioral traits, and minor shifts in the process of interaction at crucial points may lead to wide divergence in phenotypes. Preconceived ideas on the locus of such crucial points often prove to be invalid. A spiral-like development toward marked dissimilarity in behavior may arise as a result of influences at all stages from the chromosomal to the postnatal ones. Conversely, similar development is often found to exist in two egg twins.

The statistical value of investigating twins, with primary genetic factors maintained constant, does not preclude more intensive studies in the fields of biochemical and clinical investigation. One of these studies is represented by the co-twin control method in which data are obtained from a few selected pairs of one egg twins. Their reactions and patterns are compared under different life conditions or in response to planned differences in management. In general, the careful study of discordant or dissimilar identical twin pairs may furnish important findings. Often the discordance turns out to be only a partial one, and much is learned about expressivity. In other cases, the divergent development may be associated with certain key life factors.

Psychiatric Genetics

Schizophrenia. In the early literature of psychiatric genetics, there are a number of case reports tending to confirm the common notion that psychoses tend to run in families. However, such studies, which were popular in the last century, are now thought to have limited value. At the time of their origin, the science of genetics itself had not yet been developed,

and the reports themselves were usually restricted to families containing many cases and to observations that in no way ruled out intrafamilial causes other than those of a genetic nature.

Expectancy rates. In 1916, Rüdin, in Germany, insisted upon the need for studying the genetics of schizophrenia in representative and clinically homogeneous samples. His school developed the methods of obtaining statistically corrected expectancy rates for schizophrenia in relatives of schizophrenics as compared with the general population. This method, the contingency method of statistical prediction, was applied first to siblings and half siblings of schizophrenics. Other investigators studied cousins, nephews, nieces, and children of schizophrenics. Kallmann's first survey, the largest major study of the genetics of schizophrenia, was published in 1939 and represented work done in the 1930's. It focused on the expectancy of this condition in a large group of descendants of schizophrenics and their siblings. Meanwhile, improved methods for ascertaining rates of schizophrenia in the general population were devised by a number of English and Scandinavian workers. All these studies showed a significant difference between the incidence of schizophrenia in the families of schizophrenic patients and that in the general population. The range of expectancy rates found in these studies was as follows: general population, 0.85 per cent; half siblings, 7 to 8 per cent; full siblings, 5 to 15 per cent; parents, 5 to 10 per cent; children of one index case, 8 to 16 per cent; children of two index cases, 53 to 68 per cent. The greater the genetic similarity to the schizophrenic, the greater was the expectancy rate. But the variations in the rates must be considered in light of the difficulties encountered in each investigation: the need to find missing family members, the differences between investigations based on hospital records and those based on direct diagnostic interviews, different diagnostic criteria in various countries, and diverse methods of age correction. Also, parental schizophrenia rates tend to vary from one population to another according to the chance of an adult becoming a parent despite certain signs of emotional instability. Most schizophrenic mothers have normal children, and many normal parents have schizophrenic offspring. There is no significant difference between the morbidity rates of the children of affected fathers and those of affected mothers. With all this, there has been widespread accord in finding that the various categories of relatives of schizophrenics show significantly higher expectancy rates than the general population.

Twin studies. As early as 1911 in the United States, twin studies were conducted with descriptions of the histories of interesting twin pairs as matters of curiosity. With progress in the accuracy of zygosity determination and psychiatric classification, data of more than historical interest were published by the early 1930's. These studies were limited in sample size. The

first large scale, unselected sample survey was planned by Kallmann in New York in 1936 and was followed by the European studies of Essen-Möller and Slater. The New York study, reported in 1946 and 1950, included 953 schizophrenic twin index cases. In this twin study the concordance rate for two egg twins was 14.7 per cent, as compared to 14.3 per cent for full siblings, 7.1 per cent for half siblings, and 85.8 per cent for one egg twins.

Deafness and schizophrenia. Another study explored the effect of early total deafness, a severe sensory deprivation, upon the vulnerability to schizophrenia. Families of patients with both schizophrenia and deafness were studied. While the schizophrenia rate among the general deaf population was no more than 2 per cent, that among the siblings of deaf schizophrenics was 12 to 14 per cent. This figure was significantly higher than that for the general population and was similar to that observed for the siblings of hearing schizophrenics. Of major importance was the fact that the schizophrenia rates between deaf siblings and hearing siblings did not differ significantly.

Mode of inheritance. Kallmann assumed that a single unit factor was responsible for schizophrenia and that this factor was autosomal recessive in nature and subject to modification by other genes conferring a greater or lesser degree of resistance. Others have favored a simple dominant mode of inheritance. In either case, auxiliary hypotheses are needed. The diversity of the various theories would seem to indicate that theories as to the exact mode of inheritance will remain inconclusive until the biochemical and physiological nature of the inherited vulnerability factor is identified.

Genetic studies and clinical psychiatry. The work of Sandor Rado and his school, based upon the genetic theory of schizophrenia, has been directed at exploring the basic psychological organization of the genetically defined schizotype. The two most consistent factors he found were a defect in the utilization of pleasure and a proprioceptive deficit.

Depressive illness

Manic-depressive psychosis. Twin-family studies have played an important role in both nosology and etiology of manic-depressive psychosis. In his classic investigation of this syndrome, Kraepelin observed large numbers of relatives who had the same illness, but he did not find an increase in dementia praecox among these relatives. The general population rate for manic-depressive psychosis in most European and American populations is not over 0.4 per cent, though in a few special situations, such as isolated island populations, rates of 0.8 and up to 1.6 per cent have been found. In the case of parents, siblings, and children of manic-depressive index cases, the rates are much higher. Some of the earlier results indicated a range of 10 to 15 per cent in the parents and a similar

range in siblings and children. Stenstedt, in Sweden, conducted a careful population study from 1949 to 1952 and found morbidity risks of 12.3 per cent for siblings, 7.4 per cent for parents, and 9.4 per cent for children.

The largest twin-family study, reported in 1950 by Kallmann in New York, involved 27 one egg and 58 two egg pairs. In this series the expectancy of manic-depressive psychosis varied from 16.7 per cent for half siblings to 22.7 and 25.5 per cent for siblings and two egg co-twins, respectively, and 100 per cent for one egg co-twins. Parents of index cases showed a rate of 23.4 per cent. The apparently perfect concordance rate of 100 per cent for one egg twins was considered an artificial maximum value, since only patients admitted to a mental hospital, and hence the most severe cases, were included as index cases.

It was concluded by both Stenstedt and Kallmann that manic-depressive psychosis followed a dominant type of inheritance with incomplete penetrance and variable expressivity of a single autosomal gene. Although there were more females than males among the index cases in both studies, the sex ratio among siblings, parents, and children was no different from that of the normal population.

An important offshoot of the study of manic-depressive illness in families was the differentiation of depressive illness from schizophrenia. In no case was a pair of twins found with a schizophrenic psychosis in one partner and a cyclic psychosis in the other, and the morbidity risk for schizophrenia among families of manic-depressive index cases was not statistically different from that in the general population.

In attempting to define the psychological characteristics of the individual predisposed to manic-depressive psychosis, Rado described a tendency to emotional overreaction from infancy, a persistent alimentary dependent state, a strong craving for gratification from without, and an intolerance to pain. He considered the depressive spell the terminal link in an etiological chain stemming from the genotype.

Involuntary psychosis. In one study, Kallmann found no increase in involuntary psychosis among the families of manic-depressives. In the families of 96 involuntary twin index cases, the risk of involuntary psychosis was increased (6.4 per cent for parents, 6 per cent for full siblings, 6 per cent for dizygotic co-twins, and 60.9 per cent for monozygotic co-twins). The risk for schizophrenia was somewhat elevated (5.5 per cent in parents and 4.2 per cent in siblings), but the risk for manic-depressive psychosis was hardly raised at all. Finally, the expectancy of involuntary psychosis among the parents and siblings of schizophrenic twin index cases was increased to 6.6 per cent.

From these data it was concluded that the diagnostic category of involuntary psychosis was more complex pathogenetically than schizophrenia and manic-depressive psychosis but that it was more closely

associated with the group of schizoid personality traits than with manic-depressive psychosis.

Deafness and depressive illness. The modifying effect of incidental factors on depressive symptoms was indicated in the New York survey of persons with early total deafness. The survey showed no significant increase or decrease in manic-depressive or involuntary psychosis, but it did show a decrease in symptoms of retardation, guilt, and depression in the presence of the early sensory deficit. Paranoid symptoms or anxious agitated states without depression appeared to take their place.

Psychoneurosis. In the case of psychoneurotic behavior, genetic studies have been hampered by problems of diagnosis and the need to develop quantitative methods. Reviewing the literature, Slater found an increase in neurotic illnesses and neurotic personality traits of a like kind among relatives of obsessional neurotics, anxiety neurotics, and persons diagnosed as hysterics, with the evidence much stronger in the first of these than in the last. The evidence supported a multifactor type of inheritance with continuous, and probably multidimensional, variation in traits.

Correlation tests have been conducted, with the use of various rating scales to measure neuroticism. In a twin sample tested with the Minnesota Multiphasic Personality Inventory, Gottesman found either a low genetic component or none in neuroses with hypochondriacal and hysterical elements, but he found a substantial genetic component in those with elements of anxiety, depression, obsession, and schizoid withdrawal.

Criminality. Some of the earlier findings in the area of criminal behavior indicated concordance rates of 14 per cent in opposite sex pairs, 54 per cent in same sex two egg pairs, and 66 per cent in one egg pairs, suggesting the importance of both family milieu and basic personality traits in shaping the habitual criminal. Unfavorable environmental influences would appear to play a large part. Further studies measuring concordance as to specific personality traits likely to lead to a life of crime rather than criminal behavior itself would seem to be indicated.

Male homosexuality. The question of the genetic contribution to male homosexuality is presently under active debate, and more research is urgently needed. Early hypotheses in this field centered about the conception that male homosexuals may have a female chromosome structure. Certain investigators found a greater proportion of males among the siblings of male homosexuals than would be normally expected. However, with the onset of sex chromatin studies and karyotype analyses, no abnormalities in sex chromatin or sex chromosomes were discovered in male homosexuals. Nevertheless, Slater more recently found a later birth order and a high maternal age in a group of 401 consecutive admissions of male homosexuals. These findings were considered to suggest a chromo-

somal anomaly in some male homosexuals. Klinefelter's syndrome has been associated with a number of cases of homosexuality, transvestitism, and pedophilia, but these symptoms are not generally characteristic of the syndrome.

Twin studies. Some of the highest one egg concordance rates have been those for homosexual behavior in the adult male. In Kallmann's series of 44 male homosexuals, almost perfect concordance was found, whereas in 51 two egg male homosexual twins, the degree of concordance in the co-twin was no higher than what might be anticipated on the basis of Kinsey's statistics for the general population.

These findings were interpreted as suggesting a gene-controlled disarrangement between male and female psychosexual maturation patterns. In this formulation, homosexuality would appear to be a part of the personality structure rather than directly determined by the gonadal apparatus. If this is so, the processes whereby this deviation develops may be studied within the interactional framework of psychiatric genetics. A normal rate of maturation of personality development and an ability to perceive and respond to sexual stimuli, to recognize satisfaction and success, and to utilize these experiences as integrating forces may be crucial to normal sexual role development. Vulnerability factors in these areas may render an individual susceptible to deviant behavior, which is then reinforced accidentally or by family or social surroundings.

A few one egg twin pairs discordant for homosexual behavior have been discovered who also showed important similarities, principally in psychological test findings that indicated sexual confusion and body image distortion. Divergent patterns of experience may be influenced by such factors as differences in the twins' relationships with their parents, frustration in heterosexual contacts, and poor masculine identification in the case of the homosexual twin. The study of many additional cases of this kind may eventually yield a detailed interactional synthesis.

Genetics of Behavior

In the realm of general behavior, there has been a steady and increasing body of data, originating in psychiatric observation of basic differences among individuals, in which the clinician himself has been led to the hypothesis of genetic or constitutional uniqueness.

Integration of genetics in psychodynamics. The science of psychodynamics was always postulated by some psychoanalysts to be part of a unitary conceptual scheme in human biology. These psychoanalysts, such as Rado, analyzed behavioral variations in the gene-specific physiological (i.e., biochemical) context of the organism. In such a scheme the psychodynamic approach, focused on an understanding of motivation and emotional control, may uncover and delineate behavior problems that require for their complete explanation the clarification of the role of genetic transmission. Indeed, this approach was formulated in the

writings of Freud. He always took into consideration both the constitutional and accidental causes of neurotic disease, and he spoke of primary congenital variations in the ego and in the defense mechanisms an individual selects. And in an early essay on the study of twins, Hartmann wrote of personality structure as the result of interaction between heredity and environment. He considered the possibility of character *anlagen* that, in the course of development, differentiate into character traits. He felt that twin studies might throw light on the possible substitution of one trait for another.

Such an integrated approach may assume a central role in future psychodynamic work. In essence, this approach affords an opportunity to recognize fundamental genetic differences among individuals and to correlate these differences with various forms of developmental interaction both before and after birth. Although the role of genetics is not always made explicit in these studies, there are many advantages and potentialities within the scope of workers who combine the methods of both disciplines.

Child studies. In the field of infant and child psychiatry, the integrated approach is becoming very fruitful and pertinent. Intrinsic differences among children have been found to be as powerful as maternal attitudes in determining final behavior patterns. These differences have been measured in various ways. Attention has been paid to sleep, feeding, and sensory responses, to activity types, to motor behavior, and to specific reaction patterns. Variations in drive endowment and reactions to stimuli have been shown to differ. The responses of neonates to various internal and external stimuli are under investigation. Genetic analysis will be the next step in studies of this kind.

Geriatric and animal studies. At the other extreme of human life, normal and pathological phenomena of senescence have been shown to have significant genetic components, as evidenced by studies of twins and their families. Finally, animal research has indicated variations between different strains in such species as mice, rats, and dogs and has applied selective breeding methods to produce extremes of behavioral characteristics.

Demographic and Social Problems

Many demographic problems fall within the scope and interest of the psychiatrist. Dysgenic trends in human populations include wars, certain differential reproductive patterns, improvement in the efficiency of therapeutic procedures not accompanied by directed guidance as to reproduction, and such mutagenic procedures as exposure to radiation. The effects of migration, of socioeconomic drift, and of differential fertility are constantly in the forefront of discussions regarding trends in the prevalence or distribution of psychiatric disorder.

Reproductivity of schizophrenics. There is current concern with the reproductivity of schizophrenic

parents. Available data clearly indicate the increased risk of schizophrenia in the offspring of such parents, ranging from over 10 per cent, if one parent is affected, to over 50 per cent, if both are affected. Modern treatment methods in the past two decades have lessened the amount of time a schizophrenic patient remains in the hospital. At the turn of the century, the reproductivity rate of schizophrenic patients was about half that of the corresponding general population. This ratio increased only slightly through the 1930's. However, in a study of reproductivity changes between 1934 to 1936 and 1954 to 1956 (based on large samples of schizophrenic patients in New York), the rate in the earlier period was 58 per cent that of the general population, but in the later period it was 87 per cent that of the general population. Moreover, there seemed to be a similar increase in reproductivity for the siblings of the schizophrenic patients in the sample. About 2 per cent of the patient marriages were between two schizophrenic patients. If the reproductive rate of schizophrenics is approaching that of the general population, any selective disadvantage that schizophrenic illness may have had in terms of its evolutionary history may now be in the process of disappearing. This fact alone spurs the search for methods of preventing and treating this condition. Meanwhile, these data are available for marriage and parenthood counseling of the many families who request such guidance. The developmental hazards of children born into homes in which one or both parents are schizophrenic include overwhelming proportions of broken homes, displacements, and chaotic lives during many rehospitalizations of the parents, in which both the child and the parent are harmed. Many individual tragedies may be avoided if sound guidance is available when requested by patients and their families.

Genetic Counseling

In clinical practice the final common pathway of increased knowledge in the areas of genetics and family guidance is the responsible practice of marriage and parenthood counseling when there is a gene-borne condition present in one of the families concerned. When doubt exists regarding important and emotion-laden decisions as to marriage and parenthood, people must have access to trained professional advisers who are able not only to elicit the facts and evaluate them scientifically but also to resolve fears and misunderstandings and to be aware of the impact of their procedures upon their patients.

Genetic counseling may represent a short term course of psychotherapy based on psychological understanding and conducted according to established techniques of psychiatric interviewing. The counselor must be well versed in the medical, legal, and psychological implications of such procedures as contraception, sterilization, abortion, artificial insemination, and adoption. From the clinical point of view, responsible genetic counseling provides the most direct

application of medical knowledge in the field of genetics to the patient and his family.

Suggested Cross References

For more detailed descriptions of the various clinical syndromes discussed in this section, see Chapter 15 on schizophrenia, Chapter 17 on the depressive psychoses, Chapter 22 on mental retardation, and Section 26.3 on homosexuality.

Section 40.1, Chess's section on the adjustment reactions of children, in the child psychiatry area (Area H), deals more fully with the constitutional behavioral reactions mentioned in this section.

2.2 NEUROCHEMISTRY

WILLIAMINA A. HIMWICH, Ph.D.

HAROLD E. HIMWICH, M.D.

Although one of the primary objectives of this textbook is to study the abnormal behavior of patients with mental disturbances, normal behavior must also be examined, if only to permit comparison of the nor-

mal individual with the disturbed patient. In the attempt to gain insight into behavior, neurochemical findings in the normal individual must be studied as well as biochemical changes accompanying abnormal behavior. We have not attempted to provide a complete survey of neurochemistry in this section; it is devoted to dealing with neurochemical data available on the human brain and to summarizing data too recently published to be available in textbooks.

Normal Brain Constituents and Cerebral Metabolism

Developing brain. The growth and development of the brain, including the attainment of the adult levels of metabolism and of the various chemical constituents, proceeds in all species of animals from the time of the appearance of the neural streak until maturity. The chronological relation of this maturation to events such as implantation, birth, and opening of the eyes varies in the different species of animals. There are some indications that the newborn human is more mature than the newborn rat, rabbit, cat, and dog. However, development after birth appears to proceed more slowly in man than in other species studied.

The changes in water, lipid, and protein composition that occur in the human brain during the first few years of life are similar to those in other animals (see Figure 1). The infant human brain reaches its adult level of deoxyribonucleic acid (DNA) at about 1 year of age. The percentage of ash in the cerebral hemispheres decreases progressively from the 3rd month of conceptual life to birth. The development of succinic dehydrogenase and the ability of the human brain to maintain oxygen consumption during fetal life suggests the same neurophylogenetic pattern that has been established for other animals. Specifically, this means that the older

parts of the brain, the medulla oblongata, for example, mature before the cerebral cortex. Although these data are only general indications, they suggest that the human brain develops in the same fashion as does that of the other animal species but not necessarily on the same time table.

The brain of the fetus shows a distinctive cerebroside pattern by the 8th fetal month. By the 3rd fetal month the gangliosides show an adult type of pattern, which may be changed by birth trauma, with marked reduction of trisialogangliosides and disialogangliosides. This change is possibly due to a rapid liberation of sialic acid due to anoxemia.

Bertler found both norepinephrine and 3,4-dihydroxyphenylethylamine (dopamine) in the 5-month-old fetus, although dopamine was not present at the end of the 1st trimester. At 5 months of fetal life, dopamine was very low. By 8 months, dopamine had increased nearly to the level found in the adult human brain. Although norepinephrine had also increased by 8 months, its rate of increase was not as high as that for dopamine. These data suggest a different maturation pattern for norepinephrine and dopamine. Hornykiewicz has suggested that the newborn human infant's relative development of the hypothalamus and related autonomic functions, as compared with the extrapyramidal motor functions, may account for the difference in the maturation patterns of norepinephrine and dopamine.

Mature brain. Analyses of adult brains are more frequent than similar work on fetal brains. Of the many constituents of the adult brain that have been studied, variations in some appear to be particularly relevant to normal and abnormal behavior. Below is a brief review of the brain constituents for which there are analyses of human brain available.

Minerals. In spite of the fact that the mineral content of the human brain would be expected to change slowly after death, there have not been many studies of adult human brains. Among the analyses that are available are those for copper, magnesium, rubidium, barium, silicone, strontium, phosphorus, and iron. Copper is of special importance because of its relation to Wilson's disease. This element reaches its peak concentration at about the same time brain growth is complete, that is, 19 or 20 years. In general, the copper content of gray matter is two to three times higher than that of white matter. The substantia nigra and the locus coeruleus are particularly rich in copper.

The very important role of the electrolytes, Na^+ , K^+ , Ca^{++} , Mg^{++} , and Cl^- , in neural transmission is discussed elsewhere in this book.

Lipids. Table I gives the currently accepted classification of the lipids in the brain. Cerebrosides are typical myelin lipids, as shown by the predominant amount of cerebrosides in white matter as compared with the cortical gray matter. In the cerebral cortex, the localization of cerebrosides cannot be restricted to the few visible myelin sheaths. Undoubtedly, these substances are also localized in the membranes of myelin-free nerves and the membranes of nerve cells themselves. Cerebrosides also play a part in the formation of the cell membrane in the glial cells. Thus, they should be considered as membrane lipids. Gangliosides, on the other hand, are localized in the nerve cell bodies and probably also in dendrites and axons. It seems unlikely that gangliosides normally occur in glial cells.

The fatty acid composition of human cerebrosides from four regions of the brain shows that the content of these substances differs from region to region, as does the relative content of hydroxy acids. However, the distribution of acids within each class is independent of brain location. The normal saturated acids contain stearic and lignoceric as major acids, but fairly large amounts of C_{22} , C_{23} , and C_{25} acids are also present. The hydroxy-saturated acids are similar but contain

 - 1. Glycerophosphatides (phosphoglycerides)
 - Phosphatidylcholines (lecithins)
 - Phosphatidylethanolamines
 - Phosphatidylserines
 - Plasmalogens (phosphatidylethanolamines)
 - Cephalin B
 - 2. Inositol phosphatides (phosphoinositides)
 - 3. Sphingomyelins (phosphosphingosides)
- B. Glycolipids
 - 1. Cerebrosides (glycosphingosides)
 - 2. Cerebroside sulfate esters (sulfatides) } Sphingolipids
 - 3. Mucolipids
 - Gangliosides
 - Strandin
- C. Nonsaponifiable lipids
 - 1. Sterols
 - 2. Hydrocarbons
- D. Neutral fat (triglycerides)
- E. Protein-bound lipids
 - 1. Proteolipids
 - 2. Phosphatidopeptides
 - 3. Lipoproteins

^a Taken from Rossiter, R. J. Chemical constituents of brain and nerve. In *Neurochemistry*, K. A. C. Elliott, I. H. Page, and J. H. Quastel, editors, p. 10. Charles C Thomas, Springfield, Ill., 1962.

little hydroxystearic acid; the unsaturated acids of both classes contain the C_{24} acid as the major constituent.

Myelin has a higher lipid content than white or gray matter, 78 to 81 per cent, as compared to 49 to 66 per cent and 36 to 40 per cent, respectively. This substance also contains higher percentages of cerebrosides and cholesterol and lower percentages of ethanolamine, glycerophosphatides, and choline glycerophosphatides than gray matter. The molar percentages of serine glycerophosphatides are reported to be about the same in each tissue. The extramyelin portion of white matter has a lipid composition similar to that of myelin but quite different from that of gray matter.

The fatty acid composition of sphingomyelins from gray matter is quite different from that of sphingomyelins from white. Before myelination, C_{18} -saturated acid is the predominating acid in both gray and white matter. The proportion of very long chain acids (C_{22} to C_{26}) in white matter increases with age and reaches about 70 per cent when the process of myelination is complete.

O'Brien et al. analyzed brain lipids, especially cerebroside sulfate esters or sulfatides, in human gray and white matter. The major fatty acids are C_{24} -saturated, and C_{24} -monounsaturated. Odd chain fatty acids are present as well as mono-unsaturated acid of both odd and even chain fatty acids, but no polyenes were detected.

By far the most extensive work on the human brain throughout life has been by Bürger, who investigated 378 brains obtained from autopsies on individuals ranging in age from birth to 90 years. According to his data, the weight and the volume of the brain attains a maximum during the 3rd decade, averaging 1,394 gm. in the male; at the age of 90 the volume of the brain is reduced to an average of 1,161 gm. As brain substances are lost, the percentage of nitrogen and protein falls (see Figure 2). DNA and ribonucleic acid (RNA), which form part of the liponucleoproteins, also diminish. The concentration of brain lipids is impaired in old age. This

change applies to all lipid fractions with the exception of a small one, the "rest lipid," which enlarges slowly to the 8th and 9th decades of life, at which time it composes about 8 per cent of the total lipids. This "rest" fraction appears to be made up in part of a yellow lipoprotein that accumulates and becomes widespread in old age. The water content of various brain parts reveals a phyletic order, the oldest areas being the driest. In addition to these differences, the decrease in water content in general throughout the early decades of life is reversed during the senium. The early fall may be ascribed chiefly to loss of extracellular water as myelin is laid down. The late increase is due mainly to an enlargement of the extracellular compartment, for the intracellular one probably decreases.

Amino acids and proteins. Relatively few analyses of human brain in regard to amino acid content or proteins per se have been made. Some information is available regarding the proteins which are contained in the lipoproteins. Data also are given on the total protein in human brain in Figures 1 and 2.

Miscellaneous substances in human brain. Biotin is important because it appears to be involved in lipid metabolism. Disorders of lipid metabolism are among the most studied abnormalities of human neurochemistry. The differences in biotin content among brains tend to be greater than among regions in the same brain. When values are based on dry weight, the highest concentrations are found in gray matter.

CHEMICAL BIOMORPHOSIS OF THE HUMAN BRAIN
MALE & FEMALE AVERAGES

FIGURE 2. Changes in brain constituents and brain weight. Brain constituents are calculated on a basis of dry weight, whereas the weights of the entire brain include all constituents as well as water. (Adapted from Bürger. From Himwich, W. A., and Himwich, H. E. *Neurochemistry of aging*. In *Handbook of Aging and the Individual*, J. E. Birren, editor, p. 187. University of Chicago Press, Chicago, 1959.)

This difference disappears when values are placed on a fresh weight basis. The human brain has been shown to contain arabinose and xylose as well as glucose and galactose.

Biogenic amines. The distribution of the various catecholamines in the human brain suggests that dopamine plays an important part in the functioning of the extrapyramidal motor centers. This conclusion is based on these facts: (1) Dopamine occurs almost exclusively in the corpus striatum. (2) Its level is reduced in Parkinson's disease. (3) L-Dihydroxyphenylalanine (a precursor of dopamine) has a beneficial effect on the akinesia of Parkinson sufferers. Dopamine occurs principally in the structures related to involuntary motor function, for example, the basal ganglia and the substantia nigra (see Figure 3). Within the basal ganglia most of the material is found in the phylogenetically youngest part of these structures. Homovanillic acid, a metabolite of dopamine, exceeds 1 μ g. per gram in the caudate nucleus, the putamen, the globus pallidus, and the substantia nigra. The data on dopamine and homovanillic acid for the globus pallidus suggest that a high dopamine turnover may occur in this region, though very little dopamine accumulation occurs.

The recent large body of work on the cellular localization of the monoamines, although done largely in the rat, contain suggestive data on how these substances exist and function in the central nervous system. Dopamine, noradrenaline (NA), and serotonin (5-HT) are present in specific neurons, largely in the mesencephalon. The fibers arising from neurons containing dopamine go primarily anterior, those from NA neurons go both cephalad and caudad, and those from the 5-HT neurons go principally down the spinal cord. The NA

and 5-HT fibers descend from the medulla and possibly higher levels. The localization of 5-HT nerve cells is entirely different from that of NA or dopamine nerve cells. The former are almost exclusively in the raphe nuclei; the latter cells are generally in a more lateral position.

Enzymes. Enzyme studies have been particularly difficult to conduct in man because of the changes that occur after death. However, certain enzymes have been studied in the human brain. For example, the distribution of diphosphopyridine nucleotide-diaphorase in the human brain has been mapped by the excellent histochemical techniques of Friede. This enzyme shows a tendency toward a caudo-cranial differentiation in the chemical architecture of the brain. The thalamus and cerebral cortex are the most variable regions. The pattern of distribution of the diphosphopyridine nucleotide-diaphorase is almost identical with that of succinic dehydrogenase and of capillarization in the medulla oblongata. Previous material suggests a similar distribution of cytochrome oxidase and triphosphopyridine nucleotide-diaphorase. The patterns appear to follow the general gradations of tissue oxidation and energy metabolism. This knowledge can be applied to problems of neuropathology, since the mapping of the deposition of lipofuscin, a pigmented lipid in the aging human brain, shows that its extent is proportional to regional gradations of oxidative enzyme activity. This fact has led to the suggestion that the deposition of lipofuscin is proportional to the "wear and tear" in an area, that is, to the intensity of the oxidative energy metabolism.

The distribution of alkaline phosphatase, acid phosphatase, and nonspecific esterase in human nervous tissue shows that alkaline phosphatase is present in the vessel endothelium, the arachnoidal cells, and the external part of the first cortical layer. It is present in the cytoplasm, the nuclei being negative. Acid phosphatase and nonspecific esterase are seen in the cytoplasm and the processes of neurons and normal glial cells, and the nuclei are negative. Acid phosphatase in the human cerebellar cortex is found primarily in the cytoplasm of Bergmann cells. Some activity is also present perivascularly and in the cytoplasm of Purkinje cells, and in Golgi cells. Carbonic anhydrase in the human brain has been determined in 32 anatomical parts. The distribution in gray matter roughly parallels the metabolism of the area, as indicated by comparison with blood flow, rates of oxygen consumption, and distribution of succinic dehydrogenase. The high activity of carbonic anhydrase in subcortical white matter suggests a special function for this enzyme.

The distribution of acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE) has been followed in the human brain by the Warburg manometric technique and Koelle's histochemical method. The AChE activity is consistently higher than the BuChE activity in gray matter. AChE is active, in increasing order, in the cerebral cortex, cerebellar cortex, thalamus, globus pallidus, and caudate nucleus. The BuChE activity is higher in white matter than in gray matter, and the AChE activity is primarily present in a granular pattern in the protoplasm of the neurons. The distribution of cholinesterase activity in white matter is diffuse. The cholinesterases of human spinal fluid and the brain have also been studied by means of electrophoresis and chromatography. Three cholinesterases are present: two butyrylcholinesterases and one acetylcholinesterase. The electrophoretic mobilities of these cholinesterases, compared with those in plasma, suggest that the acetylcholinesterase in spinal fluid derives from the brain. No decision can yet be made as to the origin of the butyrylcholinesterases.

The highest activity of glutamic acid decarboxylase is also present in the extrapyramidal motor system. As yet no data are available on the relationship of this enzyme to extrapyramidal motor syndromes.

Because of the uneven distribution of the biogenic amines, interest has grown in the patterns of concentration of the

FIGURE 3. Noradrenaline and dopamine in the human brain. (From Bertler, A. Occurrence and localization of catecholamines in the human brain. *Acta Physiol. Scand.*, 51: 97, 1961.)

enzymes responsible for their elaboration and destruction. The activities of L-dihydroxyphenylalanine (L-dopa) decarboxylase and monoamine oxidase do not correspond with the distribution of the respective amines.

These relatively sparse data indicate the areas of research in human brain chemistry of greatest interest at the present time. The data on lipids seem promising, as explanations of the various lipid degenerative diseases can be based on the abnormalities of lipid structure and composition. The biogenic amine distributions are important in clarifying neurological diseases such as parkinsonism. Moreover, the effects of psychotropic drugs on these compounds promise to aid in our understanding of their action and of the fundamental chemistry of the conditions in which they are effective.

Cerebral metabolism. (The normal adult brain uses about 3.5 ml. of oxygen per 100 gm. of brain per minute. For a human brain of average weight, this is a total consumption of approximately 50 ml. of oxygen per minute, or about 20 per cent of the basal oxygen requirement of the body as a whole. With age and degenerative disease there may be a decrease in cerebral metabolism (see Table II). (The evidence is good that the intact brain utilizes glucose predominantly as a normal substrate for energy, with no evidence of significant utilization of other substrates for this purpose. Glucose is essential for the complete normal functioning of the human brain, and few substances, if any, can substitute for glucose in this respect, even under unusual circumstances.) Cerebral blood flow on an average in the normal alert subject is 54 ml./100 gm./minute; in the sleeping subject it is 65 ml./100 gm./minute. Glucose consumption is 5.4 mg. 100 gm. minute. (On the basis of whole brain, blood flow averages 750 ml. per minute, oxygen consumption 46 ml. per minute, and glucose consumption 7.6 mg. per minute.)

Disorders Affecting Brain Constituents and Metabolism

Anoxia. (The brain is basically dependent on its supplies of glucose and oxygen. For this reason, the two most important things that can affect the brain are anoxia and hypoglycemia.)

Impairment of oxygen supply may be caused by a failure of any link in the long chain of events beginning with the inspiration of air and ending with a final utilization of oxygen by the tissues. It may occur because of (1) insufficient oxygen in the respired gases, as in high altitudes, (2) obstruction of respiratory passages, or (3) failure of the respiratory centers. The carriage of oxygen from the outside air to the tissues can be impaired by myocardial insufficiency, reduction of the oxygen carrying power of the blood, decrease of blood pressure (as in shock), relative cerebral ischemia, or enzymatic inactivation at the cellular level. (Even if oxygen is available and all of the processes concerning it are normal, the require-

ment may be relatively excessive, as during convulsive seizures.)

(Anoxia results in an impairment of the energy supply to the brain. It can be withstood successfully for only about 5 minutes in the adult.)

(Anoxia is an important problem in the neonate.) In fact, there is some tendency for all disorders of the newborn to be ascribed to anoxia or to birth injury. Chronic anoxia, often beginning in utero, may lead to various neurological disorders and to death. However, there are reports on one child who withstood anoxia for 14 minutes with no apparent damage and on another child who recovered from a lack of oxygen

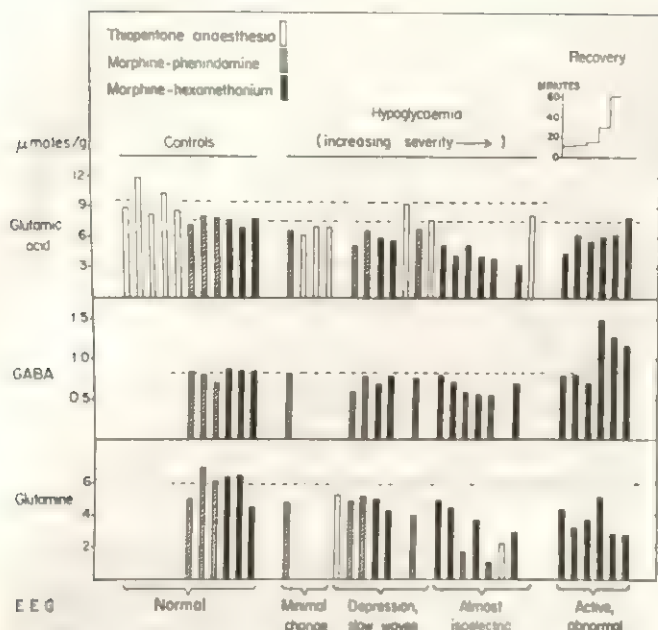

FIGURE 4. Changes in cerebral glutamic acid, GABA, and glutamine in relation to electrographic patterns during hypoglycemia and recovery. Dotted lines represent mean control values. (Taken from Tews, et al. Chemical changes in the brain during insulin hypoglycaemia and recovery. *J. Neurochem.*, 12: 688, 1965.)

after 25 minutes. It is difficult to distinguish between the effects of anoxia per se and of concomitant pathological processes of different origins in the fetus. Animal studies have cast some light on this problem, but it is still one that needs a great deal of research.

In any animal suffering from anoxia, survival depends largely on the release of energy from anaerobic processes. A small yield of energy is made available as substrates containing unsaturated hydrogen bonds accept hydrogen atoms from compounds that are thus oxidized to yield energy. Such compounds include unsaturated fatty acids and the sulfhydryl-containing compounds. Glycolysis, or the anaerobic breakdown of carbohydrate, especially of glucose, is the most important source of anaerobic energy. In accordance with the Embden-Meyerhof scheme, glucose is broken to form pyruvic acid and, finally, lactic acid. Glycolysis is a wasteful process in comparison with oxidation; in glycolysis 12 molecules of carbohydrate supply approximately the same amount of energy as the oxidation of 1 molecule of that substance.

Another important anaerobic source of energy comes from the breakdown of energy-rich phosphate bonds, such as those contained in phosphocreatine and adenosine triphosphate. These and similar energy-rich compounds are built up by the energy derived from glycolysis, and the latter process is reversed, as most of the lactic acid formed anaerobically is reconverted to carbohydrate by the energy released in oxidations. If glycolysis is stopped for any reason, energy-rich phosphate bonds are depleted as a sec-

ondary result. This depletion, however, is not complete; a small amount of energy-rich material remains.

Tews and Stone studied the effect of anoxia induced by the administration of 4.5 per cent oxygen in nitrogen for 12 to 13 minutes in adult dogs. There were significant increases in alanine, γ -aminobutyric acid (GABA), glutamic acid, leucine, tyrosine, and lactic acid, accompanied by decreases in aspartic acid. Remaining unchanged, however, were most of the free amino acids and related compounds (see Figure 4).

Hypoglycemia. In hypoglycemia the brain first makes use of the glycogen it has stored in the central nervous system. Figure 5 shows the changes in glycogen content during insulin hypoglycemia in nine experimental dogs. In general, the upper parts of the brain lose their glycogen deposits before the lower areas are depleted. After the glycogen stores are gone, the brain then makes use of whatever material may be available for energy. The depletion of glycogen in the brain is followed by a reduction of material such as glutamic acid. Such a condition can be obtained only if the animals are given artificial respiration and have some means of maintaining their body temperature. The use of glutamic acid to supply energy does not, however, support the electrical activity of

FIGURE 5. Glycogen content of parts of the central nervous system of hypoglycemic dogs. Observations of nine experiments are presented here. A line has been drawn to separate the glycogen contents of the animals into two divisions. The values to the left of the line are significantly lower than the lowest values for the normal range for the same part. Those to the right are not significantly lower than the normal. In general, the upper parts of the brain lose their glycogen deposits before the lower areas are depleted. (Taken from Chesler, A., and Himwich, H. E. Effect of insulin hypoglycemia on glycogen content of parts of the central nervous system of the dog. *Arch. Neurol. Psychiat.*, 52: 114, 1944.)

the cortex, even though 50 per cent of the glutamic acid remains. Other amino acids are also affected by hypoglycemia (see Figure 6). If the animal is kept alive long enough, functional and structural changes occur in the brain.

The changes that occur in insulin hypoglycemia have also been analyzed from the standpoint of the mineral content of the brain. Yannet, Geiger, and associates have shown that a marked loss of potassium and an increase in sodium occur with insulin hypoglycemia. The cats used by Yannet also had marked neurological defects. Acetylcholine is lowered in the brain in hypoglycemia.

Convulsions. Convulsions are some of the most dramatic and interesting phenomena that the medical practitioner sees in his patients. Although there has been a great deal of clinical research in the field, relatively little if any work has been done on the changes in the human brain before, during, and after a convulsion. Most of the work in this area has been done with convulsions induced experimentally in animals.

With methionine sulfoxamine (MSO) at 6 mg. per kilogram, the dog does not always have convulsions, even though there is evidence of toxic reaction. Under these conditions there is the expected decrease in glutamate and glutamine, due probably to inhibition of glutamine synthetase. The values for methionine and cystathione show a disturbance in methionine metabolism due to the MSO. The inhibition of glutamine synthetase by MSO leads to the reduction of protein synthesis in cerebral tissues, which can be reversed if methionine is given before or shortly after MSO treatment. The effects of the convulsive hydrazids seem to be related to GABA, glutamic acid decarboxylase, the GABA- α -ketoglutarate transaminase, and vitamin B₆. GABA is reduced in vivo by convulsive hydrazids whereas hydroxylamine raises the level and tends to reduce cerebral excitability. Five significant changes occur in cerebral constituents with these compounds: GABA is decreased, and its precursor, glutamate, shows a trend toward a higher value, although this difference is not statistically significant. Alanine, ammonia, lactate, and tyrosine are increased. The data by Tews and Stone are compatible with the suggestion that the seizures caused by drugs that inhibit glutamic acid decarboxylase or GABA- α -ketoglutarate transaminase result from the reduced rate of metabolism through the GABA pathway.

In animals treated with picrotoxin or pentylene-tetrazol (Metrazol), neither of these convulsants produces a striking effect on the free amino acid content of a brain frozen while a seizure is in progress. Picrotoxin causes a slight reduction in aspartic acid; with Metrazol, the change is not significant. Animals given fluoroacetate and fluorobutyrate have also been studied, since both compounds cause violent seizures and alterations in the content of cerebral constituents. With both of these substances, significant

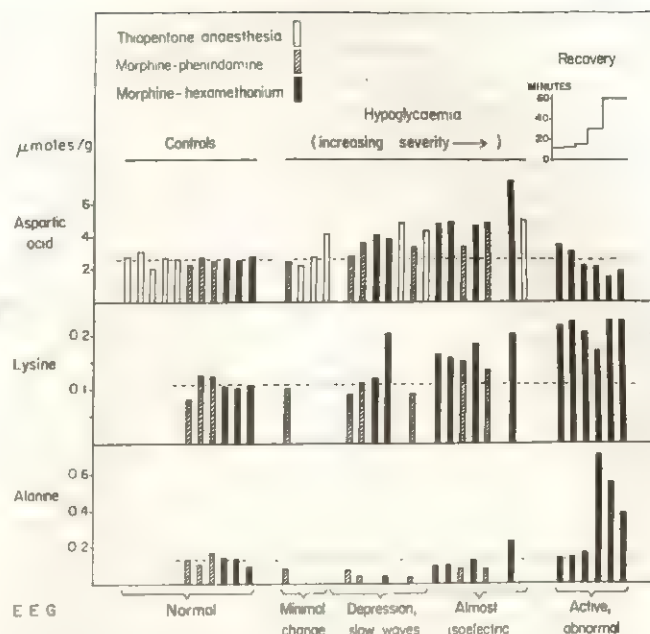

FIGURE 6. Changes in cerebral aspartic acid, lysine, and alanine in relation to electrographic patterns during hypoglycemia and recovery. Dotted lines represent mean control values. (Taken from Tews, et al. Chemical changes in the brain during insulin hypoglycaemia and recovery. *J. Neurochem.*, 12: 689, 1965.)

changes are found for alanine, ammonia, citrate, lactate, leucine, and serine. Decreases are noted for aspartic acid, glutamate, and glycogen. These fluoro compounds block the tricarboxylic cycle prior to the ketoglutarate oxidase step and produce a decrease in glutamic and aspartic acids. Decreases in brain glycogen have been observed during seizures induced by fluoro compounds, in contrast with Metrazol, in the dog. Probably convulsions per se do not reduce brain glycogen, except in a transient fashion. If blood glucose and cerebral circulation are adequate, the normal value is soon restored.

In studying a group of epileptic and nonepileptic mice, Naruse and his co-workers showed that ammonia, glutamate and glutamic acid were low in the brains of the epileptic mice, and GABA was 40 to 50 per cent higher. The level of total acetylcholine was 40 to 60 per cent higher than in the control strain, and the rate of resynthesis of acetylcholine was faster.

The human epileptogenic cerebral cortex has been studied by Tower. The biochemical lesion seemed to involve an inability to build up bound acetylcholine, a metabolic loss of glutamate in incubation in vitro, and reversal of normal potassium and sodium levels. These data were used as a basis for the treatment of epileptic patients.

Seizures have been linked to carbonic anhydrase by Millichap, who studied susceptibility to seizures in young animals as related to the activity of this enzyme. However, Robinson and Tizard pointed out that many other factors, such as dendritic development and

myelinization, may be of equal importance in permitting the propagation of abnormal discharges. Nonetheless, a parallel can be demonstrated in adult animals between the degree of carbonic anhydrase inhibition and the degree of anticonvulsant activity.

Lipidoses. Lipidoses, abnormalities of lipid metabolism, are an enigmatic group of disorders which provide a fertile field for future study.

Tay-Sachs disease. A large study headed by Korey included both biochemical and electron microscopic analyses of brains of patients with Tay-Sachs disease. These patients were assessed clinically and then subjected to cerebral biopsy. These investigators found that the neuronal cytoplasm was crowded with distinctly laminated bodies that had no apparent association with normal cellular organelles. The macroglia pericytes and the endothelial cells contained degraded lipid. Myelin degeneration was of the Wallerian type, and the phagocytes contained myelin fragments and lipid bodies. Fibrous astrocytosis and an increase in extracellular space developed as the disease progressed. Biochemical studies of Tay-Sachs disease are complicated by the occurrence of the disease in a rapidly developing brain, showing both maturational changes and effects secondary to the primary pathology of the disease. Gangliosides were found to accumulate within the cells, not only in gray but also in white matter. An increased hexosamine content of cerebral tissues was also characteristic of the condition and possibly reflected the presence of asialo derivatives of gangliosides. In the early stages of the disease, brain slices showed normal respiration and lipid formation. A decrease in the free amino acid pool, however, occurred in the central nervous system, which may limit protein synthesis. Although the enzymes present in homogenates of diseased brains were capable of acting on normal brain, Tay-Sachs brain, or beef brain, there may be structural abnormalities in some of the gangliosides in Tay-Sachs disease that make them resistant to hydrolysis by enzymes in the diseased brain tissue. The membranous cytoplasmic bodies (MCB) have been isolated from homogenates of Tay-Sachs brain and analyzed for lipids. The data of Samuels and his colleagues, who attempted to form MCB in an artificial system, suggest that these bodies are neither lysosomes nor derivatives of normal organelles, but may result from spontaneous aggregation of gangliosides, cholesterol, and phospholipids to form a molecular complex.

Leukodystrophy. Austin has described the biochemical changes in the globoid leukodystrophy (GLD), which is a fatal, genetically determined disorder of myelin that chiefly affects infants and children. The most consistent finding was an increase in the ratio of cerebrosides to sulfatides. The data, however, showed that GLD brains contain the usual amount of cerebrosides; the condition, therefore, is not, strictly speaking, a cerebroside lipidosis. However, the possibility of focal disproportional dyslipidoses should not be overlooked. This may appear as

an increase in cerebrosides relative to sulfatides where there are islands of globoid elements. In the globoid bodies there were relative increases in cerebrosides identified as cerebron and kersasin. These increases were always in relation to a marked decrease in sulfatides and were usually evident in relation to the sphingomyelin as well. Fractions with higher globoid counts contained more than four times as much cerebrosides as sphingomyelins. The results suggest that the GLD fractions may share in the lipid imbalance in a manner similar to that of the globoid bodies.

Metachromatic leukodystrophy (sulfatidosis), studied by Svennerholm, shows a decrease of all lipids in the brain, especially cerebrosides, but an increase of sulfatides. The primary lesion may be the defective anabolism of cerebrosides with secondary increased formation of sulfatides.

Gaucher's disease and Niemann-Pick disease. In Gaucher's disease, a systematized storage disease of the reticuloendothelial system involving deposition of cerebrosides in liver and spleen, there are clinical signs of central nervous system involvement. Gaucher cells have been found in the adventitia of the blood vessels, but no increase has been detected in the brain. Niemann-Pick disease, on the other hand, involves storage of sphingomyelins in reticuloendothelial tissues. So far, analyses of the sphingomyelins found have shown no difference from the normal. Analyses of brains in both Gaucher's and Niemann-Pick diseases show a low concentration of myelin lipids, and the fatty acid analysis of sphingomyelins have an immature pattern.

Demyelinating diseases. The interest in lipidoses extends to the demyelinating diseases as well. Control glial fractions from advanced multiple sclerosis cases show relatively less sphingolipid than do glial fractions from GLD, whereas glial fractions from less advanced diffuse disseminated sclerosis have relatively more. In multiple sclerosis, there appear to be changes in the lipids of the brain; that is, there is a deficiency of the plasmalogens of the total phospholipids. Analyses of the carboxyl esters and the long chain fatty acids reveal even-numbered saturated fatty acids in visually intact white matter. Phospholipids seem to be reduced in concentration, possibly because of a predemyelinating removal in the very early stages of degeneration. The appearance of cholesterol esters in the white matter of patients with multiple sclerosis is also of interest, since the appearance of these compounds is one of the earliest and most characteristic features of Wallerian degeneration.

Edema. Brain edema is thought to occur following neurosurgical procedures and in the areas adjacent to brain tumors in patients who have received electroshock. Little can be done to study the human brain under these circumstances, and so the effects of edema on brain composition must be inferred from animal studies.

Anoxia produced in any way apparently causes

rapid swelling of the brain, with an increase in intracranial pressure. When edema was produced by means of distilled water perfusion in monkeys and rabbits, the edematous brain contained more sodium and more water, especially in the white matter, but less potassium. Carbohydrate metabolites were altered in such a way as to indicate increased anaerobic glycolysis. The data obtained by Herschkowitz et al. suggest that the edema was mainly in the white matter, probably within the myelin sheath, and perhaps some in the extracellular space. When edema is produced by means of an experimental glioma in the mouse, the tissue adjacent to the implanted tumor becomes edematous, with an increase in water and sodium content. The chief alteration detected by electron micrography was a swelling of glial cell processes. It is suggested that there is altered membrane permeability or altered transport process.

Edema has also been produced in cats by a number of procedures, such as freezing treatment to the exposed dura and partial removal of brain tissue. Fluid did not accumulate as a result of reflection of the dura and simple exposure of the brain, but 24 hours after the production of a lesion by freezing, there was a decrease in dry weight, a fall in potassium, and an increase in sodium. These alterations occurred only in the white matter and persisted for at least 5 days. As far as the cortex as a whole is concerned, there were no changes. Three days following partial lobectomy, the same changes as with a freezing lesion were noted. A highly significant correlation occurred between sodium and potassium content. Cortisone apparently had no effect, although the authors were not able to rule out the possibility that the volume of tissue that was edematous was diminished in cortisone-treated animals.

Neurochemistry in Psychiatric Disorders

Sources of information. Only rarely does the opportunity arise to make neurochemical and other basic observations on the brains of patients with cerebral disorders. There is still too little application of the multidisciplinary approach, and, therefore, a dearth of basic observations on the various disorders of the brain and mind. And, unfortunately, there are limitations on the information available from even the living patient. In the foreseeable future, researchers will find the greatest difficulty in obtaining biopsy materials for biochemical studies from the brains of living patients. Significant autopsy material is easier to obtain, but the information so obtained is similar in some ways to that available from neurohistological methods in general: The end results of a process can be seen, and the mechanisms may be inferred, but the various intermediary steps in that process cannot be observed and studied. But at least this inferential information presents suggestive leads. A step removed from the brain is the information to be obtained from the patients' blood and urinary constituents, which may be of indicative value. (For

example, in schizophrenic patients, an increase of urinary tryptamine foreshadows a worsening of schizophrenic symptoms, and a return to the usual tryptamine levels similarly precedes the cessation of the exacerbation. The increased urinary excretion of tryptamine only mirrors the increased levels of tryptamine in the blood, and since the blood-brain barrier is permeable to tryptamine, a rise in the brain concentration of tryptamine may be inferred.)

The permeability of the blood-brain barrier to tryptamine has, however, been established by animal experimentation, and this leads us to another step still further removed from the primary source of the information sought, the human brain. In animal studies, researchers may try to imitate disease in man; for example, they may establish high levels of phenylalanine in an attempt to reproduce phenylketonuria and then study the effects of excessive phenylalanine on developmental behavior and changes in the brain constituents.

The following discussion examines all the aforementioned devices for examining the biochemical correlates of behavior; however, the most compelling data should be obtained from the brains of living patients.

Chemical findings on patients with disturbed mental functioning

Schizophrenia. Although the role of biological alterations in the pathogenesis of schizophrenia has been under investigation for many years, both experimental results and their interpretations remain controversial. One of the main problems is that schizophrenia is poorly defined and may cover a variety of pathogenic conditions. Even in individual patients, the clinical symptoms may vary greatly from time to time. Moreover, the dissimilar clinical responses to treatment with psychotropic drugs suggest that different biochemical situations may prevail in the various clinical states.

It is easy to understand why each new technique based on advances in the basic sciences is applied in turn to a study of schizophrenia, a prevalent disease that is emotionally crippling and costly, both financially and in interpersonal relationships. Many biochemical studies, however, not only failed to correlate the basic observations with the behavior of the patients, but failed to use controls, including the important one of diet. Later work, done under improved conditions, indicated an impaired ability of the liver to detoxify psychotomimetic substances and a reduced turnover rate of some phosphate compounds in the blood of schizophrenic patients. Investigations have also disclosed dissimilarities in urine and blood constituents between schizophrenic patients and controls.

Tryptophan. One aspect of biochemical psychiatry is concerned with the relationship between schizophrenic behavior and the protein products contained in urine. Some studies on urinary derivatives of

TABLE III

*Urinary Tryptamine and Degree of Psychotic Activity**

The average for all observations lies within the normal range but other averages, based on the degree of psychotic activity, reveal an increased output of tryptamine per day with greater degree of psychotic activity.

Degree of Psychotic Activity	No. of Patients	Days	Tryptamine ^b	
			Average	Range
			μg./day	
Apparently inactive.....	17	410	91.6	39-137
Slightly active.....	12	270	124.9	58-167
Moderately active.....	7	105	151.2	66-282
Active.....	6	40	202.8	153-292
Markedly active.....	2	10	382.5	180-585

^b Average, 118 μg. per day for 835 24-hour urinary specimens. Normal range, 36 to 120 μg. per day.

tryptophan have revealed abnormally high excretions of indole substances in patients with schizophrenia in comparison with nonschizophrenic individuals. But, in other observations, either no differences were found or these products in the urine of patients with schizophrenia were abnormally low. It seems apparent, however, that the daily excretions of these urinary products exhibited a greater variability in schizophrenic patients than in normal controls. A series of studies on schizophrenia showed, not unexpectedly, that average values for urinary indoles were either within the normal ranges or were somewhat higher than in controls. But when day-to-day correlations were made between the intensities of the psychotic symptoms and the levels of the urinary constituents, striking agreements were observed between the degree of psychotic activity and the daily output of tryptamine (see Table III) and of 3-indole acetic acid and 5-hydroxyindole acetic acid. Tryptamine was the most sensitive indicator for the rise of the indole products in the urine. From 1 to 5 days before any signs of behavioral exacerbations were observed, indole substances began to increase in the urine. Levels continued high until rather precipitous falls were observed, usually beginning before the last day of active psychotic behavior. Examination of the results revealed that the increased indole products were endogenous. Such a conclusion was drawn partly on a basis of behavioral changes but chiefly on biochemical alterations. Behaviorally, some patients suffered a loss of appetite and simultaneously exhibited greater motor activity. Thus, caloric intake decreased at a time when caloric requirements were raised. Biochemically, the additional indole products in the urine were the result of the breakdown of body proteins.)

Increases of urinary creatinine revealed that the breakdown of muscle protein was one source of the increased indole products. But another factor account-

ing for the endogenous origin must also be given serious consideration. Figure 7 shows the known pathways of tryptophan metabolism in the body. When the use of the pathway starting with formylkynurenine and ending with 1-N-methylnicotinamide is depressed, those of the indoles may show compensatory increases. Thus, two processes may be operative in the increased urinary excretion of indoles. But the diversion of tryptophan metabolism away from the formylkynurenine pathway and toward that of the indole amines does not exclude the increased breakdown of body protein as another source. In both cases, greater amounts of tryptophan breakdown products would appear in the urine. A number of other amino acids, including methionine, may also be released from muscle. It is, therefore, possible that higher concentrations of indoles and methionine may give rise to an increased production of psychogenic methylated indoles, thus accounting in part for the maintenance of the active psychotic behavior.

In a series of feeding experiments with methionine, tryptophan, and other amino acids, it was shown that, given by themselves, none of the amino acids evoked changes in the behavior of schizophrenic patients. Even with a monoamine oxidase (MAO) inhibitor, all but two were without effect. When, however, me-

* = Normal urinary excretion products.

** = Found in large amounts in the urine in vitamin B₆ deficiency.

FIGURE 7. Known pathways of tryptophan metabolism in the body. Note that three of these pathways maintain the indole nucleus intact but that the fourth one, via kynurenine, does not. (Adapted from Figure 1 of Olson, R. E., Gursley, D., and Vaster, J. W. Evidence of a defect in tryptophan metabolism in chronic alcoholism. *New Eng. J. Med.*, 263: 1169-1174, 1960.)

thionine was administered simultaneously with a monoamine oxidase inhibitor, significant changes occurred as the severity of symptoms increased. These changes were first observed by Pollin, Cardon, and Kety and were amply confirmed by other investigators. Tryptophan with an MAO inhibitor also aggravated the clinical picture, but to a lesser degree. An important function of methionine is to make methyl groups available for the metabolic processes of the body. Since another methyl donor, betaine, also produced behavioral worsening when administered with an MAO inhibitor, it seemed that tryptophan metabolites and methionine might be involved in a common mechanism, a mechanism in which increases of indoles derived from tryptophan and elevated levels of methyl groups donated by methionine might facilitate the formation of methylated indoles with psychogenic properties. It is worthy of note that *N*-dimethyltryptamine, similarly derived from tryptophan and methionine, is also psychotomimetic.

Thus, two factors may be involved in the mechanism of symptomatic deterioration of schizophrenic patients: the psychogenic action of methyl groups and the increased formation of indoles. Increases of

tryptophan and methionine may act together to produce an endogenous metabolic factor by furnishing material for the production of a methylated psychogenic indole. Such a psychotomimetic substance may be involved in this hypothetical cycle in an individual with a genetically determined schizophrenic reaction; from his hereditary nexus comes an unknown initiating component of the behavioral worsening, with loss of appetite as an early symptom. Next follows a breakdown of muscle protein and the release of amino acids, including tryptophan and perhaps methionine. In addition, more indole amines are formed from tryptophan at the expense of the kynurenine metabolites. These amino acids, in turn, furnish materials for the formation of a methylated psychogenic indole, an endogenous metabolic factor. Finally, the interactions of the endogenous factor and the schizophrenic hereditary component increase the severity of the psychotic symptoms.

Catecholamines. Phenylalanine and tyrosine are the sources of all the catecholamines in the body, including dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline) (see Figure 8). Increases of urinary catecholamines usually accompany

FIGURE 8. Pathways of catecholamine metabolism. The process starts with phenylalanine and goes on to tyrosine, dopa, and dopamine. Noradrenaline (norepinephrine) gives rise to adrenaline (epinephrine). At this point, there are two chief paths for the continuation of the metabolic process. In extraneuronal areas, these two substances are transformed into normetadrenaline (normetanephrine), metadrenaline (metanephrine), and reactions catalyzed by catechol *O*-methyltransferase). Within the neuron, dihydroxymandelic acid is formed with the aid of monoamine oxidase. In both instances, however, these products are next acted upon by the other one of these two enzyme systems so that, irrespective of the order in which the two enzymatic processes occur, the resulting product is the same, vanilmandelic acid. (Courtesy of H. E. Himwich.)

aggravations of psychotic symptoms but, unlike the indoles, do so on a somewhat different temporal basis. The indoles begin increasing *before* a sudden flare-up of symptoms and continue at high levels during psychotic activation. On the other hand, epinephrine and norepinephrine begin rising *simultaneously* with the increase of psychotic behavior.

Usually, exacerbations of schizophrenic symptoms are accompanied by increased motor activity, heightened tension, or both. In such instances, both urinary catecholamines and indole amines appear in greater amounts. But when signs of anxiety and tension increase in severity in the absence of marked worsening of schizophrenic symptoms, the catecholamine rise is not associated with a rise of the indoles. In the elevation of catecholamines unaccompanied by an elevation of indoles during a period of reduced psychotic activity, the relationship between the greater output of the catecholamines and the increased anxiety and muscular activity in schizophrenics does not appear to be different from the relationship between the increased excretion of catecholamines and heightened tension and motor restlessness in non-schizophrenic individuals.

The methyl groups in the formation of psychotogenic indole amines have been stressed here, but a similar possibility exists with the catecholamines. Osmond and Smythies suggested that a catecholamine related to mescaline may play a part in schizophrenia, and they included in their paper the remarks of Harley-Mason that such a catecholamine might arise as a result of faulty methylation. More recently, Friedhoff and Van Winkle have demonstrated that dimethoxyphenylethylamine (DMPEA), a catecholamine, is closely related in chemical structure to the well known psychotomimetic agent, mescaline (trimethoxyphenylethylamine). And DMPEA occurs more frequently in the urine of schizophrenic patients than in nonschizophrenic populations. Much work has been done following this lead, which, however, like that of the psychotogenic indoles, is still regarded as controversial. Yet the conclusions of Friedhoff and Van Winkle have received much experimental support.

DMPEA may represent a nosological classification characteristic of certain types of schizophrenia, and the increases in the other catecholamines—noradrenaline, adrenaline, and vanilmandelic acid—may correlate with hyperactivity and anxiety. But this correlation is not specific for patients with mental disease, since it also occurs in normal subjects. The alterations of the indole amines, on the other hand, seem to relate specifically to the worsening of the schizophrenic symptoms.

Steroid hormones. In some ways, the changes in the urinary steroid hormones parallel those of the catecholamines. Sudden and severe exacerbations of schizophrenic symptoms are accompanied by rises in both 17-ketosteroids and 17-hydroxycorticosteroids.

Ratings of the severity of schizophrenic symptoms reveal that the levels of urinary steroid hormones may be associated with concomitant high degrees of motor activity and anxiety.

In a specific example (see Figure 9), a most severe exacerbation of schizophrenic behavior was accompanied by outbursts of violence, hostility, and hyperactivity. All urinary constituents studied, with the exception of vanilmandelic acid, rose during the behavioral worsening. The episode lasted for 5 days, with peak exacerbations on the 1st and 2nd days, but psychotic symptoms were most severe on the 3rd day.

These simultaneous observations of urinary indoles, catechols, and steroids during behavioral worsening have made it possible in many instances to separate psychotic symptoms in accordance with their relationships either to urinary indoles on one side or to urinary catechols and steroids on the other. One group of symptoms, characterized by rises in catechols and steroids, is composed of increased motor activity or motor restlessness, heightened tension, and anxiety. In contrast, a second group of symptoms is distinguished by increases of urinary indoles and is associated with such psychotic symptoms as intensifications of hallucinatory and delusional experiences, usually with mounting hostility. When to the latter group of symptoms are added motor restlessness and increased anxiety, either separately or together, all three classes of urinary products are significantly elevated in the urine. Perhaps the elevations of catecholamines and steroids indicate a total mobilization of the bodily resources to meet this grave emergency.

Affective disorders. The most prominent experimental concept on the affective disorders emanates from Kety's laboratory and indicates that some, if not all, depressions are associated with an *absolute or relative deficiency of catecholamines*, particularly of norepinephrine in the brain. Abnormal elation conversely may be accompanied by an excess of such amines. The experimental basis for the hypothesis is found in the work of Brodie and his associates, who correlated behavioral excitation in animals with increased levels of brain norepinephrine. Other workers were able to demonstrate that dopa, a catecholamine (but not serotonin), counteracts reserpine-induced sedation in animals. In the clinical field, Schildkraut also demonstrated that depressed patients treated with imipramine showed increased excretion rates of normetanephrine, a catecholamine metabolite, with clinical improvement. In contrast, according to some studies, sedation seems to be associated with a greater abundance of brain serotonin. However, other data do not support the hypothesis that fluctuations in catecholamines are the primary biochemical factors in depression.

An alternate dualistic approach, presented by Buono, Pscheidt, and Himwich, suggests that *both catechol and indole amines* are involved in the bio-

FIGURE 9. Excretion patterns. Urinary excretions of catecholamines, indole amines, and steroid hormones during periods of aggravation of schizophrenic symptoms in patient J. F. (From Berlet, H. H., Bull, C., Himwich, H. E., Kohl, H., Matsumoti, K., Pscheidt, G. R., Spaide, J., Tourlentes, T. T., and Valverde, J. M. Endogenous metabolic factor in schizophrenic behavior. *Science*, 144: 311, 1964.)

chemical basis of the affective disorders. This hypothesis accounts for several important clinical and experimental observations. The "somatization" of the depressive illness is adrenergic in quality and includes tachycardia, insomnia, anorexia, anxiety, and abnormalities in the digestive tract as well as in the sexual sphere. All these signs are strikingly similar to the amphetamine-induced organic psychoses. On the other hand, melancholia with its depression of vital functions, lack of interest, decreased vitality, and delusional ideas of guilt and hopelessness may be the result of disturbances in indole metabolism. Experimentally in animals, the dualistic hypothesis finds support in recent work using chronic treatment with MAO inhibitors, which block degradation of serotonin and catecholamines, combined with reserpine, which releases serotonin in its active form. These studies disclosed that behavioral and electroencephalographic activation can be related to disturbances in the balance between serotonin and norepinephrine; behavioral stimulation was associated with increases of brain serotonin while there was either a smaller rise or even a decrease in brain norepinephrine. Working with various mammalian species, different workers have also pointed out the importance of the equilibrium between both amines. Clinically encouraging results were obtained by Mendiguita and Penasco in the

management of endogenous depressions using reserpine with an MAO inhibitor. Investigators have correlated clinical improvement in depressive patients, who improved with reserpine and imipramine, but not with imipramine alone, with variations in indole metabolism and not in catechol turnover.

Metabolic disorders. Psychotic behavior and disorders of tryptophan metabolism have been observed not only with schizophrenia but also with a disorder of metabolism, Hartnup's disease. The similarities among the psychotic manifestations of Hartnup's disease, pellagra, and schizophrenia are worth noting. In this regard, a metabolic linking of homocysteinuria with schizophrenia has been suggested.

Hartnup's disease. This disease is associated with intermittent and variable malfunctions, including psychosis, cerebellar ataxia, migraine headaches, and, occasionally, progressive mental retardation. Comparatively late, a dermatitis develops. Like the dermatitis in pellagra, it is a red, scaly rash occurring chiefly on surfaces exposed to the sunlight. Hartnup's disease is characterized by biochemical alterations, including a generalized amino aciduria, except that proline, cysteine, and taurine remain within normal limits. The excretions of other catecholamines are at least 10 times the usual values. In the absence of elevated levels of these amino acids in the blood, this amino aciduria is ascribed to leakage through the kidney, probably due to defective reabsorption in the renal tubules.

A second biochemical defect is impaired absorption of

tryptophan from the intestine. For that reason, tryptophan breakdown products (3-indole acetic acid, 3-indole acetylglutamine, and indican) accumulate in the intestinal lumen. These products are then absorbed in the blood stream and eliminated in the urine. A decrease of nicotinamide occurs as a result of the poor absorption of tryptophan. This may account for the pellagra-like features of Hartnup's disease. During clinical remissions, the metabolic abnormalities recede.

Pellagra. The multideficiency of pellagra includes lack of tryptophan, nicotinic acid, and perhaps other vitamins, including pyridoxine. The behavioral changes sometimes observed in pellagra may strikingly reproduce the clinical pictures of schizophrenia. Not long ago, patients with pellagra were sent to mental institutions with a diagnosis of schizophrenia. In man, pellagra is also linked to the genetically determined disorder of Hartnup's disease by changes in tryptophan; abnormally high urinary excretion rates of indole metabolites have been observed, and tryptamine has been isolated from the urine of pellagrins.

Homocysteinuria. This syndrome is associated with the presence in the urine of homocysteine, a metabolite of methionine, and is characterized by such relatively constant features as mental retardation, fair hair, dislocated ocular lenses, malar flush, peculiar gait, and genu valgum. More variable features of this syndrome are excessively long extremities and digits, convulsions, thrombotic incidents, cardiovascular disorders, and fatty liver. Though resembling Marfan's syndrome in exhibiting pectus excavatum or carinatum, and ectopia lentis and arachnodactyly, it differs from Marfan's syndrome by the presence of mental retardation, malar flush, and osteoporosis.

Homocysteinuria is inherited as an autosomal recessive gene. Liver biopsies of homocysteinuric patients reveal that the enzymatic pathway fails to function because of a lack of activity of the enzyme cystathionine synthase. In view of this close metabolic association between methionine and the other members of this pathway and in view of the observation that the administration of either methionine or cysteine to a schizophrenic patient receiving a MAO inhibitor worsens the schizophrenic symptoms, it is of interest to point out the pedigree of a homocysteinuric female patient. Her mother, brother, sister, maternal grandfather, maternal grand uncle, and maternal grand aunt were all probably schizophrenic. Another patient, who had been diagnosed as having schizophrenia, was found on further study to be suffering from homocysteinuria. At present, however, the question of whether metabolic relationships between methionine and homocysteine are of etiological importance in the schizophrenic patient can be regarded only as a suggestive lead for research.

Wilson's disease. This disease is also known as hepatolenticular degeneration; the latter name is descriptive of the morphological pathology, which usually includes degeneration of the corpus striatum with cirrhosis of the liver. The characteristic symptoms include difficulty in swallowing and in speech, irritability and explosive behavior, and a progressive organic dementia. The chemical pathology is concerned with an altered distribution of copper, with abnormally high amounts in the cerebrospinal fluid, urine, brain, liver, and kidney. Total blood copper is significantly lower than usual. Moreover, ceruloplasmin activity is reduced.

Wilson's disease is probably associated with a genetically altered ceruloplasmin; copper is no longer held tightly bound to ceruloplasmin, a serum globulin. Despite the fact that the copper loosely attached to serum albumin is above normal levels, a decrease in the total copper content of the blood occurs. The copper of the albumin fraction is excreted in the urine and also deposited in brain, liver, and other tissues where the affinity for copper is greater. The urine contains high levels of amino acids, tryptamine, 5-hydroxyindole acetic acid, 3-indole acetic acid, and other indole metabolites in addition to the catecholamines, epinephrine, and dopamine.

Phenylketonuria. Phenylketonuria is a genetically deter-

mined condition involving a fault in the metabolism of phenylalanine, a failure in the conversion of that substance to tyrosine (see Figures 6 and 7). As might be expected, phenylalanine accumulates in all the fluids of the body, and metabolic products of phenylalanine are produced in excess. As with Hartnup's disease, excessively large amounts of 3-indole lactic acid, 3-indole pyruvic acid, 3-indole acetic acid, and indican are found in the urine; conversely, 5-hydroxyindole acetic acid is excreted at abnormally low levels.

These results may be explained by an inhibition exerted by phenylalanine on the absorption of tryptophan from the intestine. A similar explanation—impaired absorption of tryptophan—may apply to the low levels of serotonin observed in the brains of animals with experimental phenylketonuria. D. W. Woolley suggests that abnormalities of serotonin in the brain are linked to mental deficiencies and the psychoses. In addition to diminishing brain serotonin, excessive elevations of phenylalanine in the blood result in decreases in the concentrations of glutamic acid, glutamine, isoleucine, and GABA in the brain.

Another characteristic of patients with phenylketonuria is insufficient pigmentation, ascribed to an interference in the oxidation of tyrosine to dihydroxyphenylalanine, though only partial inhibition of this reaction has been demonstrated in phenylketonurics. Characteristically, patients with this disorder are blond and occasionally albino, even when they come from dark-complexioned Caucasian or Negro families.

The majority of victims have low intelligence quotients, and some never learn to talk or achieve toilet training. On the other hand, there are a few authenticated cases with intelligence well within the normal range. Convulsions start in the 1st or 2nd year of life and finally stop spontaneously. Abnormal electroencephalograms are observed even in the absence of seizures. These electrical abnormalities are reversible with diet therapy. It is striking that records of mental institutions reveal that phenylketonurics are sometimes admitted with a diagnosis of childhood schizophrenia. Older children exhibit motor restlessness, are hyperactive and may injure themselves.

For the normal development of intelligence, treatment consisting of an intake of phenylalanine reduced to about 4 to 5 per cent of the diet should be started in the first weeks of life. When the special diet may be stopped with impunity is not yet known, but it is known that a cerebral defect, once developed, is irreversible and probably involves permanent structural alterations of the central nervous system. The gray matter shows few abnormalities. In the white matter, in contrast, there are usually multiple areas of defective myelinization. In these patients, the pigmentation of the substantia nigra and the locus caeruleus is decreased, although these areas are normally pigmented in albinos.

Maple syrup disease. Maple syrup disease is so named because the urine of the patient has a striking odor similar to maple sugar. The nervous system deteriorates rapidly, and in most instances death occurs within the 1st month of life. The severe brain damage characteristic of this disorder is limited chiefly to the white matter, and myelination is defective. The inborn error of metabolism is transmitted as an autosomal recessive gene and is characterized by a failure in oxidative decarboxylation of four keto acids: α -ketoisocaproic acid, α -ketoisovaleric acid, α -keto- β -methyl-n-valeric acid, and, probably, α -ketobutyric acid. The metabolic deficiency occurs in the enzyme that catalyzes the conversion of α -ketoisocaproic acid to isovaleryl coenzyme A. In addition, there is a secondary rise in the keto acids, and the respective amino acids, including leucine, isoleucine, alosileucine, and valine, all of which also appear in the urine.

Blood-Brain Barrier

Knowledge of the blood-brain barrier is based almost entirely on animal experimentation. Hence the characteristics of the human blood-brain barrier can

only be inferred from clinical studies and results on animals.

Selectivity of the barrier. Although equilibrium is rapidly established between the vascular fluids and the interstitial fluids of most organs, many substances show a slow equilibration in the brain. Moreover, the brain is more accessible to certain substances if they are administered intrathecally than if they are given intravenously. An excellent example is the response to sodium ferri-cyanide. Given intravenously, this substance produces no symptoms, even in fairly high concentrations, nor can it be detected in the brain, although it penetrates all other tissues of the body. When, however, small amounts of ferri-cyanide are introduced into the cerebrospinal fluid, the animal develops pronounced symptoms and may die of convulsions. Thus, the intrathecal injection has circumvented a barrier between blood and brain. Consideration of the blood-brain barrier is of great importance in many problems, including the utilization of food stuffs by the brain, the therapeutic use of drugs, and the pathological effects of viruses and toxins on brain tissue. [In discussing all these problems, the four fluid compartments in the brain and the barriers between them must be considered.]

The acid aniline dyes (negatively charged) fail to enter the brain, although the basic aniline dyes (positively charged) do so readily. Not only the negatively charged dyes but also substances such as lactic acid and pyruvic acid, containing electronegative carboxyl groups, enter the brain slowly. The rate of entrance of these substances into the brain is considerably slower than that of glucose and is too slow to allow them to support brain metabolism. In contrast, observations on excised cerebral tissue reveal that lactic acid is as effective as glucose in maintaining brain metabolism. In excised tissues the blood-brain barrier is destroyed, and materials penetrate the brain easily at the cut surface.

Most ions, whether electropositive cations or electronegative anions, require a relatively prolonged period before equal concentrations are present in the blood and in brain tissue. Many studies have shown that anions such as bromide, iodide, thiocyanide, and chloride have a short equilibration period, usually only a few minutes, between the circulatory fluids of the vascular tree and the interstitial fluids of the various organs. Yet equilibration with the brain may not be complete after 3 hours. Sodium and potassium are the classical examples of cations that enter the brain slowly. Radioactive sodium concentration, for example, equalizes throughout the vascular and interstitial fluid of the various organs of the body within 11 minutes, and yet it requires 62 hours to attain equilibrium between brain and blood. Though potassium enters interstitial fluids more rapidly than sodium, this rate is slower for the brain than for other organs.

Only a few amino acids have been studied extensively in terms of their ability to pass the blood-brain barrier. These include glutamic acid, leucine, isoleucine, lysine, tyrosine, tryptophan, and phenylalanine. The ability of these substances to penetrate the brain is greater in the young animal than in the adult. Recently, it has been demonstrated that an increased blood level of one amino acid can influence the entrance of other amino acids into the brain. The most striking example is the inhibition of the uptake of tryptophan and tyrosine by a high blood level of phenylalanine.

Variations in the barrier. Not all parts of the brain are equally protected by the blood-brain bar-

rier. A portion of the hypothalamus with the pituitary and pineal glands, the choroid plexus, and the area postrema are more permeable than other areas. Nor is the permeability of the blood-brain barrier a constant factor. The barrier appears to exert less influence, and that on fewer substances, at the time of birth and probably in fetal life than in later life. The physiological status of the brain is also important. Any injury to the brain tends to reduce the resistance of the blood-brain barrier to penetration. Inflammation facilitates the passage of substances. Considerable evidence has accumulated that an increase of carbon dioxide reduces barrier function. There is also the possibility that the rate of permeability may be regulated in part by non-nervous tissue. It has been found that, using the perfused brain of cats, the administration of glucose fails to revive the brain unless an extract of liver is added at the same time.

Nature of the barrier. Many explanations have been offered for the existence of the blood-brain barrier. The current point of view is that what has been called the blood-brain barrier concept is not a generalized phenomenon. It is probably a summation effect of many factors, only some of which are integral parts of the boundary between blood and brain. The work in this field in the last 10 years leads largely to the conclusion that there will be no generalized concept developed to fit all the phenomena and that each condition and each metabolite must be considered by itself.

Dobbing, however, has suggested a unified hypothesis that postulates a multiplicity of factors, including those the brain has in common with other tissues and those that make the brain the specialized tissue it is. In the first group, Dobbing includes electrical charge, molecular size, degree of dissociation, extent of protein binding, and lipid solubility of the substances being considered. The second group consists of the negligible extracellular space in the brain, with consequent necessity for transcellular transport and the resistance to entry of substances into metabolically inert compartments. Brain metabolism, then, would dominate much of the transport of substances between blood and brain. Considered in this way, the blood-brain barrier is a reflection of, rather than a limiting factor in, *in vivo* cerebral metabolism.

Anatomical explanation. Considerable research is still devoted to determining the exact location of the blood-brain barrier. Theoretically, the barrier could function at any one of several sites, beginning with the capillary wall, going outward to the peripheral lining of the perivascular space, and finally to the surface of the glial cells (see Figure 10).

The capillaries have again and again been implicated as the site of the blood-brain barrier phenomenon. Two possible elements are involved: the endothelial cells themselves and the matrix that binds these cells together. It is generally agreed that lipid-soluble substances, such as CO_2 , O_2 , urethane, and formaldehyde, diffuse easily through the endothelial cells. The portion of the capillaries traversed by lipid-insoluble substances such as water, sodium chloride, and glucose is still under dispute.

Two main camps have developed in the blood-brain barrier controversy: one supports the perivascular glial membrane theory and the other the capillary endothelial theory. At this time, experimental evidence exists in support of both positions.

In the last few years, attention has turned to the relative lack of extracellular space in the brain as a possible explana-

FIGURE 10. Semidiagrammatic section of central nervous system and investing membranes. This shows the relationships of various fluid compartments and barriers. The *enlargement at lower left* illustrates three probable sites of blood-brain barrier action: capillary endothelium, basement membrane, and perivascular glia. Note that invaginating pia does not accompany penetrating vessels, although only a few are illustrated. (From Tschirgi, R. D. Chemical environment of the central nervous system. In *Handbook of Physiology*, J. Field, H. W. Magoun, and V. E. Hall, editors, Section 1, Vol. 3, p. 1865. American Physiological Society, Washington, 1960.)

tion for the blood-brain barrier phenomenon.) The close packing of the cells in the brain results in a dearth of extracellular space, with a possible figure of less than 5 per cent being fairly well agreed on at this time. This situation means that material entering the brain has to enter a cell almost immediately, rather than entering the extracellular fluid. In contrast, in organs such as kidney and liver, the cells are surrounded by extracellular fluid, which may constitute 30 per cent of the organ. Astroglia function as a water ion compartment for the central nervous system; this compartment is involved in a selective transport of fluids and metabolites between blood and brain. These facts have led to the concept that the important factor in the blood-brain barrier may be a combination of glial cells and extracellular space, the so-called extraneuronal space.

Transport explanation. One of the most intriguing suggestions that has arisen from all of the studies of the blood-brain barrier has been the concept that the barrier may have a functional rather than an anatomical localization and may depend on transport phenomena. An active transfer linked to metabolic processes has been suggested by Tschirgi to account for transfer between blood and brain, between brain and cerebrospinal fluid, and between blood and cerebrospinal fluid.

Figure 10 indicates the possibility that a net movement of water and solutes from the vascular compartment into the extravascular compartments in the central nervous system could be balanced, at least in part, by a net movement of water and solutes from the subarachnoid space through the arachnoid villi into the blood stream. Such fluid formation depends on the local elaboration of metabolic energy in order

to explain the electrolyte composition of the cerebrospinal fluid. But the nature of this metabolic pump and its role in regulating the neuronal microenvironment are obscure.

Tschirgi has postulated a mechanism whereby sodium and chloride might be moved from plasma to the extravascular fluids of the central nervous system by an action of an exchange mechanism controlled by the carbon dioxide produced by metabolism.

This mechanism, according to his hypothesis, exists throughout the entire parenchymal perivascular membrane of the central nervous system, including the choroid plexus with the exception of the arachnoid villi in the dural sinuses. The net influx of electrolytes in water is seen as moving into the subarachnoid space and back into the blood stream largely through the arachnoid villi. Carbon dioxide, among other factors, would determine the rate. This mechanism for the transfer of sodium across the cellular membrane by exchange for metabolically produced hydrogen with the accompaniment of osmotically obligate water is essentially identical with that proposed for kidney tubular reabsorption of sodium. In the kidney, however, the pump is oriented to move sodium and water from the extravascular fluid into the plasma whereas, in the brain, Tschirgi proposed that it is positioned to move these substances from the plasma into extracellular fluid.

The transfer of substances from the blood into the brain can be compared to the renal tubular transport apparatus in the case of glucose, which is reabsorbed by means of active transport from urine to blood. When organic acids are used to study overloading, they show various inhibiting potencies on the blood-brain barrier. A rough correlation can be drawn

between their ability to inhibit blood-brain barrier transport and their maximal tubular rate of excretion.

The various factors that can influence the blood-brain barrier are shown in Table IV.

Current Research in Neurochemistry and Behavior

The early and voluminous work of Bennett and his group on cholinesterase and behavior or intelligence in rats has recently been confirmed by Kling, Finer, and Nair in regard to the effects of handling and light stimulation on the developing rat brain. This work points out the importance of sensory stimuli on the biochemical development of the brain. This field will undoubtedly prove a fertile one for investigation and will also mean that workers in the field of brain development will have to check and control environmental stimuli if their data are to be evaluated properly. Levine and Alpert had earlier reported the effects of handling on the phospholipids of the developing brain.

The studies of the effects of learning on the RNA of the brain have been reported from Hyden's laboratory. Unfortunately, his elegant methods of nucleotide analysis have few practitioners, and his findings await confirmation from other laboratories. Work on memory and its relation to RNA and to the hippocampus is being pursued from a number of points of view. The transfer of memory of a learned task by administration of RNA or a fraction of the RNA from a trained animal to a naive one is being vigorously pursued. The probable low permeability of the blood-brain barrier to RNA as such increases the complexity of the problem. Flexner and his colleagues have used puromycin to destroy recent memory in the hippocampus. This approach appears quite promising.

Ever since γ -aminobutyric acid was described as an inhibitory substance, many attempts have been made to correlate its inhibitory effects with behavior. The most successful experiment was by Jasper, Khan, and Elliott. They were able to demonstrate that the fluid from the surface of the brain contained more GABA when the electroencephalographic pattern showed sleep spindles than when arousal tracings were seen. More recently Wiechert and Herbst were able to provoke convulsions by upsetting the balance between glutamic acid and GABA.

Suggested Cross References

Many psychiatric disorders and symptoms are mentioned in this section with regard to associated biochemical findings. These include schizophrenia, the affective disorders, various lipidoses, demyelinating diseases, various forms of mental deficiency, epilepsy, and pellagra. More detailed information regarding these topics may be found under their respective titles in Area D, which deals with neurology, and

TABLE IV
Summary of blood-brain barrier phenomena^a

1. Lipophilic substances	Passive diffusion	No blood-brain barrier
2. Hydrophilic metabolites	Specific transport mechanisms ^b	
Nutrients (glucose, certain amino acids)	Blood \rightarrow CNS	Partial blood-brain barrier (above transport capacity)
Waste products (organic conjugated ions, indicator dyes)	CNS \rightarrow blood	Blood-brain barrier (counter-transport)
3. Hydrophilic non-metabolized nonelectrolytes (inulin, sucrose, mannitol)	No transfer	Blood-brain barrier (passive)

Blood-Brain Barrier Phenomena and Effects of Injuries on It

1. Injuries	Causing free diffusion or flow (mechanical, necrotizing or otherwise rupturing)
Indicators:	Detectable native or foreign blood constituents in general
2. Injuries	Causing functional alteration of specific transfer mechanism(s)
Indicators:	Substances presumed to be specifically handled by the actual mechanism(s)
Examples:	a. General transport inhibition: decreased CNS uptake of glucose "increased uptake" (abnormal blood-CNS passage) of acid dyes b. Selective (overloading) inhibition of CNS-blood extrusion of "waste acids": abnormal blood-CNS passage of acid indicators only

^a From Steinwall, O. Blood-brain barrier dysfunction: Some theoretical aspects. *Acta Neurol. Scand.*, 40: Suppl. 10, p. 25, 1964.

^b Carrier-mediated, saturable (limited transport capacity), inhibitable by competitive overloading or by unspecific toxic influences.

Area F, which covers the psychiatric disorders. Further information regarding chemical hypotheses relating to schizophrenia is discussed by Weiner in his section on the etiology of schizophrenia (Section 15.3), while Cohen's article on the manic-depressive psychoses (Section 17.1) contains references to the chemical aspects of the affective disorders. Further information regarding the anatomy and physiology of the various brain structures which are referred to in this section, as well as the subject of synaptic conduction and the neural transmitters, may be found in Sections 2.5 through 2.9. The following section on psychopharmacology by Harold Himwich contains information regarding the influence of psychotropic drugs on the brain constituents discussed in this section.

2.3 PSYCHOPHARMACOLOGY

HAROLD E. HIMWICH, M.D.

Introduction

In this section, the ameliorative effects of psychotropic drugs on the behavior of patients with disturbed mental functioning is discussed. These drug-induced changes in behavior will be related to associated neurophysiological, neuropharmacological, and neurochemical changes. The actions of psychotomimetic agents will receive a similar analysis.

Sources and evaluation of information. The effects of drugs on human patients must be determined by observations made on man. However, electroencephalographic reactions in the structures of the limbic system must be ascertained by deep electrode implantation, and such applications on human beings are necessarily limited in number. Because it is difficult to obtain extirpations of human brain areas performed in order to explain biochemical changes induced by drugs during life, areas sensitive to psychotropic drugs have been analyzed in animal experiments. The results in infrahuman mammals cannot be extrapolated to man because differences in species may yield different results. But animal observations are suggestive in many instances. For example, a sufficient number of studies on members of many mammalian species, including man, have been performed to know that reserpine decreases brain amines in all mammals. This does not suggest a causal relationship between the brain changes produced by drugs in animals or man and the associated behavioral alterations in patients. It does, however, point out analogies between the specific effects of psychotropic drugs on the animal and human brain and the broader behavioral changes observed in patients, for example, whether the two different parameters indicate tendencies toward tranquilization. One may well take a pragmatic attitude toward the effects of drugs on patients with mental disease and compare the therapeutic values of psychotropic drugs with preparations for the control of diabetes, their dosage schedules revised in accordance with the severity of the symptoms. One need not go into the various debates as to whether psychotropic drugs cure the psychotic process or are chiefly of placebo value. The observed facts disclose the great symptomatic relief afforded to patients.

But what of the future? It is well known that, generally, the longer the patient stays in the hospital,

the worse the prognosis. It would seem that the most optimistic attack on schizophrenia is the early application of psychotropic drugs to the patient in the hospital and rapid discharge to the out-patient clinic for continued chemotherapeutic supervision.

Drugs Used in the Treatment of Schizophrenia

Reserpine. This drug, one of the two original tranquilizers, is now to a certain extent replaced by the phenothiazines. Reserpine is recommended, however, in intensifying the action of antihypertensive agents and in the management of overactive, brain-injured children.

Action. Nevertheless, reserpine subserves an important neuropsychopharmacological action: it prevents the binding of noncholinergic transmitters (for example, monoamines such as norepinephrine) to labile storage depots in intracellular granules. As a result of reserpine, the monoamines are not stored in the intracellular granules, and the concentrations of free neurotransmitters are temporarily increased. But as they are no longer protected from the action of the monoamine oxidase (MAO) enzyme, the neurotransmitters are rapidly metabolized, and the enduring effect of reserpine is to reduce the concentrations of free neurotransmitters.

These two different effects of reserpine on the concentrations of brain neurotransmitters are paralleled by biphasic actions on the electroencephalogram (EEG) and on behavior. About ½ hour after the injection of a single intravenous dose of reserpine large enough to cause depletion of serotonin and norepinephrine in the brain (1 mg. per kilogram), the EEG begins to reveal activation (see Figure 1). But about 4 to 5 hours after the injection a long continued sleep pattern appears (see Figure 1B). The initial period of EEG alerting corresponds closely to the time interval during which free monoamines are increased as the stores in the granules are diminished by the action of the reserpine. The sleep pattern occurs when the concentrations of the monoamines decrease.

When reserpine is first administered to patients, it may produce a period of worsening in the psychotic symptoms, a period of turbulence that is usually more marked and longer than that evoked by the phenothiazine derivatives. It is not unlikely that the short period of the activation of the psychotic symptoms corresponds with the time when brain amines are increased above the usual levels and that the tranquilizing action is associated with the long continued low levels of brain amines.

Site of action. The actions of reserpine on hypothalamic mechanisms are complex. It is true that noradrenergic activities are inhibited and that cholinergic activities are augmented, as observed in the constriction of the pupil and the bradycardia. One reason reserpine is not so potent in tranquilizing as the phenothiazines may be found in its stimulating action on limbic structures, which may exhibit spon-

FIGURE 1. Effects of reserpine. This shows the cortical EEG tracings from 13 animals injected with reserpine (1.0 mg. per kilogram) before surgical preparation. Note the presence of EEG activation at 1 hour (A) and its absence at 5 hours (B). Electroencephalographic tracings were also recorded after the administration of 0.1 mg. of reserpine per kilogram (C). Note the spontaneous seizures of limbic structures. Recording leads are as follows: MSS, median suprasylvian gyrus; SC, sensory cortex; ENTO, entorhinal cortex; HIPP, hippocampus; AMG, amygdala; SEPT, septum. (A and B are unpublished observations. C is from Killam, E. K. and Killam, K. F. The influence of drugs on central afferent pathways. In *Brain Mechanisms and Drug Actions*, W. S. Fields, editor, p. 88. Charles C Thomas, Springfield, Ill., 1957.)

taneous seizures with reserpine (see Figure 1C). The total effect of any medicament on behavior depends, of course, on the summation of all its influences on the brain, and with reserpine the result is less influential in the direction of tranquilization than with the phenothiazines.)

Phenothiazines. The phenothiazine derivatives constitute the largest group of psychotropic drugs. From the clinical viewpoint, there are important quantitative differences between their actions, but the qualitative similarities of the various phenothiazines facilitate their discussion as a group. Some important phenothiazine derivatives are chlorpromazine (Thorazine), triflupromazine (Vesprin), promazine (Sparine), methoxypropazine (Tentone), mepazine (Pacatal), piperacetazine (Quide), prochlorperazine (Compazine), perphenazine (Trilafon), trifluoperazine (Stelazine), fluphenazine (Prolixin, Permitil), acetophenazine (Tindal), carphenazine (Proketazine), and butyrylperazine (Repoise). They act on the mesodiencephalic activating system, including its caudal and rostral components; the reticular formation; and the diffuse thalamocortical projections. and depress them

Action

Mesodiencephalic activating system. An important component of the mesodiencephalic activating system as a whole is cholinergic in function; and, atropine, for example, can block EEG arousal caused by practically any kind of stimulus. These inhibiting effects occur because the rostral component of the mesodiencephalic activating system, arising in the diffuse thalamocortical nuclei with their thalamocortical projections, is cholinergic in part. (On the other hand, the caudal portion, the reticular formation, responds to adrenergic stimuli. This response is probably not a direct action but is due to the effects of epinephrine and epinephrine-like substances on afferent collaterals to the reticular formation.) The integrated activity of the caudal and rostral components are responsible for the EEG-alerting reactions. The blocking effect of phenothiazines on the EEG is in accordance with their cholinolytic action, even though it is much weaker than that of atropine. Figure 2 presents an example of the prevention of EEG arousal with a single dose of chlorpromazine. This blocking action

FIGURE 2. Alert EEG patterns evoked by painful stimulus and prevented by chlorpromazine and imipramine. *A*, bilateral leads taken from various cerebral structures as indicated: on right side, electroencephalographic control pattern of resting rabbit; on left side, the effects of pinching rabbit's leg. *B*, change produced by chlorpromazine (5 mg per kilogram) in electroencephalographic pattern in response to pain. Note the absence of the alerting reaction to pain. *C*, effects of imipramine HCl on EEG arousal following peripheral pain stimulation. Note that the EEG arousal response to pain stimulation is blocked after the administration of imipramine HCl, 16 mg per kilogram. (From Himwich, H. L. Anatomy and physiology of the emotions and their relation to psychoactive drugs. In *Scientific Basis of Drug Therapy in Psychiatry*. Proceedings of Symposium at St. Bartholomew's Hospital, London, September 7 and 8, 1964, pp. 3-24. Pergamon Press, London, 1965.)

may provide a basis for the alleviation of the distressing emotional cloak that surrounds noxious stimuli. It is well known that patients bear pain with less difficulty under phenothiazine therapy than without one of these drugs.

Reticular formation. Phenothiazine tranquilization also correlates with depression of the hypothalamus and midbrain reticular formation, areas containing relatively high concentrations of monoamine neurotransmitters, whose actions are inhibited by members

of this group of drugs. This hypothalamic depression is attributed to an inhibiting effect on the α -adrenergic blocking action by chlorpromazine, thus preventing the response of the postsynaptic receptor to the monoamine neurotransmitter (see Figure 4). As the blood-brain barrier is permeable to the phenothiazines, there is no reason to doubt their penetration into the hypothalamus. In addition, it has been found that the phenothiazines reduce to some degree the excitability of the extrahypothalamic limbic structures. There-

fore, the tranquilization produced by the phenothiazines seems to be associated with indirect influences on the hypothalamus and direct blocking action that prevents the reaction between the receptor sites and the monoamine neurotransmitters, norepinephrine and serotonin. Clinically, tranquilization is not specific in the treatment of schizophrenia; the drugs tranquilize irrespective of the diagnostic category and also relax people without mental disorders.

Thalamocortical projections. It is another question entirely to explain how hallucinations and delusions of schizophrenic patients are mitigated or eliminated by the phenothiazines. Because false sensory interpretations and unrealistic thinking in schizophrenic patients are favorably influenced, the therapeutic actions necessarily seem to involve neocortical functions. Because of the Papez circuit and similar reverberating feedbacks that involve both neocortical and limbic areas, the effect of the phenothiazines on the older brain parts may be indirectly brought to bear on functions allocated chiefly to the neocortex. Because of the drug-induced diminished intensity of the emotional reactions and the resulting decrease of anxiety, the defenses are no longer maintained.

Haloperidol (Haldol). This drug, a butyrophenone, acts in many ways like a phenothiazine; small doses inhibit the mesodiencephalic activating system, probably in its rostral component. Larger doses, however, evoke EEG alert patterns. Clinically, the butyrophenone is more potent than the phenothiazines in general, but severe extrapyramidal disturbances are also exhibited with it, especially in excessive dosages. In observations on rabbit brain, smaller doses were required for the butyrophenone to block EEG arousal and evoke EEG alerting than were necessary for the phenothiazines. Similarly, both chlorpromazine and haloperidol enhance the accumulations of norepinephrine and catecholamine metabolites produced by the monoamine oxidase inhibitors in the brain.

Drugs Used in the Treatment of Depression

Iminodibenzyls. These antidepressant drugs, the psychostimulants or thymoleptics, are employed best in the management of psychotic depression of endogenous origin: melancholia and the depressive phase of the manic-depressive psychosis. The iminodibenzyl derivatives, initiated with the use of imipramine (Tofranil), soon included amitriptyline (Elavil), desmethylinipramine (Pertofrane and Norpramin), and opipramol (Ensidon). Two somewhat different chemical forms of desmethylinipramine (Nor- triptyline and Vivactil) were also developed. The antidepressant effects of these drugs seem specific against endogenous depressions, and the stimulating actions on behavior of other kinds of depression and of nondepressed individuals are neither as marked nor as constant.

Monoamine oxidase inhibitors. These antidepressant drugs, the psychic energizers, secure their most favorable effects in atypical depressions in which either anxiety or hysteroid features are predominant. The monoamine oxidase inhibitors started with iproniazid (Marsilid) and now include isocarboxazid (Marplan), nialamide (Niamid), phenelzine (Nardil), and reversible ones like tranylecypromine (Parnate). Their therapeutic actions cannot be regarded as specific, for they exert euphorizing effects in individuals who are not depressed. The side reactions of the monoamine oxidase inhibitors are more dangerous and occur more frequently than those of the iminodibenzyls, but the untoward result can usually be prevented by lower dosages and appropriate medical treatment.

Phenothiazines. These drugs may exert antidepressant effects in addition to the tranquilization for which they are noted. Overall and his colleagues observed a paradoxical clinical result, a lifting of depression, with the phenothiazine thioridazine (Mellaril). A group of patients was selected on a basis of having depression as the major symptom, regardless of whether the psychiatric diagnoses fitted the usual depressive syndromes. Comparing the results of thioridazine with those of imipramine on these depressed patients, they found that there were essentially no significant differences in the salutary effects of these two drugs on the depressed patients.

Comparisons of the drugs. A study of the EEG in animals reveals that under certain conditions the members of all three groups of drugs with clinical antidepressant actions may evoke EEG alerting. It is possible that this alerting may be associated with the antidepressant clinical effects of the iminodibenzyls as well as of the phenothiazines. In regard to tranylecypromine (Parnate), this monoamine oxidase inhibitor administered in 2 mg. per kilogram doses (see Figure 3C) twice in 2 hours evoked EEG alerting.

The phenothiazines and the iminodibenzyls have a common basis for their ability to evoke EEG alerting. In contrast to the blocking effects of the acute administration of phenothiazines or iminodibenzyls, EEG arousal results (see Figure 2) if the same dosage is given chronically, day after day. Studies on chronic administration were made with four phenothiazines—chlorpromazine, trifluorpromazine, perphenazine, and trifluoperazine—and two iminodibenzyls—amitriptyline and imipramine. EEG tracings were recorded 18 hours after the last chronic dosage, and activated patterns were observed in the absence of any apparent stimulation. In most instances on the 6th day of chronic medication, and in all animals at 9 days, the EEG pattern exhibited increased spontaneous alerting. The percentage duration of alerting on these animals was greater than the percentage duration of alerting in unmedicated animals. This EEG alerting reaction is not one of paradoxical sleep but is,

FIGURE 3. Effects of chlorpromazine, imipramine, and tranylcypromine. Spontaneous EEG activation resulted from chronic medication with chlorpromazine (A), imipramine (B), and tranylcypromine (Parnate) (C). (From Himwich, H. E. Loci of action of psychotropic drugs in the brain. *Fol. Psychiat. Neurol. Jap.*, 19: 217, 1965.)

rather, associated with wakefulness. Thus, in Figure 3 the effect of the chronic administration of chlorpromazine (A) and imipramine (B) observed 18 hours after the last dose revealed alerting.

The mechanism of action of the changes produced by chronic administration involves, among other factors, drug storage, especially in brain tissue, and the more rapid rate of metabolism of the drugs by increased amounts of the drug-metabolizing enzymes. These enzymes are contained in the microsomes, and the increased concentration of microsomes occurring with chronic dosage is referred to as enzyme induction. Enzyme induction, leading to a more rapid detoxication of the drugs, has been observed for various chemical agents and may also apply to the phenothiazines and iminodibenzyls. Irrespective of the processes involved, the members of these three groups of

drugs, when given chronically, all have the ability to facilitate the stimulating effects of EEG alerting.

Only the monoamine oxidase inhibitors have the power to elevate significantly the levels of brain neurohormones. But there are also differences between the phenothiazines and iminodibenzyls. In some ways the iminodibenzyls exhibit stimulating effects not shared to any great extent by the phenothiazines. In contrast to the phenothiazines, six of the seven iminodibenzyls studied evoked spikelike activity in the subcortical structures, particularly the olfactory bulb.

Psychotropic Drugs and Cellular Metabolism

To understand the clinical effects of these drugs, one might consider their pharmacological actions at the cellular level. Imipramine and chlorpromazine have different effects on peripheral actions, as exhib-

A genetic explanation may also explain the different clinical results with the use of butyrylperazine on patients in Germany and the United States. In America the results were poorer, despite the higher dosage required. Still another confusing phenomenon in the understanding of patients is that the same disease may have different modes of expression in people belonging to different cultures.

Minor Tranquilizers Used in the Treatment of Neuroses

For patients with grave forms of the neuroses, the same drugs are used as for patients with psychoses, namely, the major tranquilizers, but not for the same reason. In neuroses, the psychotropic drugs are given for the general calming action, an antianxiety effect, rather than as specifics. Nevertheless, in the milder forms of neuroses, including neurotic or reactive depressions, the minor tranquilizers bring strong adjunctive support to psychotherapy. By diminishing anxiety and tension, they help tide the patient over particularly bad periods, characterized by disabling anxiety, that may occur during psychotherapy. They may be also administered to overcome anxiety throughout the course of psychotherapy.

Chlordiazepoxide (Librium). In usual doses, chlordiazepoxide and the related diazepam (Valium) possess valuable assets in the amelioration of anxiety, whether or not associated with somatic complaints. Thiazenone and oxazepam (Serax) are similar medicaments. One action of these drugs, accounting for the antianxiety effect, is a polysynaptic depression, which releases muscular spasms and thus indirectly diminishes the muscular tension brought on

by anxiety. In antispasmodic activity, diazepam is superior to chlordiazepoxide. Both drugs exert weak or no effects on the neocortex and neurotransmitter depots, but their antianxiety action seems to parallel their depressant influences on limbic structures—the septum, amygdala, and hippocampus. Such a depression may simulate to a certain degree the tranquilization observed with animals subjected to extirpations of these structures.

In experiments in which the amygdala was stimulated and evoked potentials taken off the hippocampus (see Figure 5), the administration of chlordiazepoxide or diazepam reduced the hippocampal responses. It is known that the amygdala and hippocampus may exert facilitatory influences upon behavior, and the elimination of such stimulation is produced by extirpation of these areas. A similar reduction of the sensitivity brought about by the depressant effects of chlordiazepoxide and diazepam may diminish the reactions to stressful influences, thus ameliorating anxiety. Such a desirable clinical response also parallels the ability of these drugs to inhibit, to a moderate degree, the alerting reaction to stimuli.

Meprobamate (Miltown, Equanil). Meprobamate calms the tense and nervous depressed patient, so frequently seen in general practice, and is also used to allay the anxiety occurring with neurotic depressions, and depressed moods of exogenous or reactive origin. In usual doses this drug does not significantly influence the discriminative functions of the neocortex or those of either component of the mesodiencephalic activating system to affect EEG patterns. Neurotransmitter depots, moreover, are not altered.

On the other hand, meprobamate exerts potent ef-

FIGURE 5. Effects of chlordiazepoxide (Librium) on spontaneous EEG recordings and evoked hippocampal responses following stimulation of the amygdala. A-1, control EEG, revealing the change from an alerting to a resting pattern (A-2), as the effect of the painful stimulus on EEG alerting is blocked by the administration of chlordiazepoxide. B-1, hippocampal responses to single shocks and repetitive stimulation of lateral nucleus of the amygdala. B-2, Response to repetitive stimulation 20 minutes after intravenous injection of 10 mg. of chlordiazepoxide per kilogram. Note gradual impairment of evoked response. (From Himwich, H. E. Loci of actions of psychotropic drugs in the brain. *Fol. Psychiat. Neurol. Jap.*, 19: 217, 1965.)

FIGURE 6. Effect of meprobamate. It shortens duration of after-discharge produced in the hippocampus by local electrical stimulation. Control record prior to drug administration is presented as well as records made 10 and 20 minutes after administration of meprobamate. Each tracing begins at the end of a stimulation period. (From Kletzkyn, M., and Berger, F. M. Effect of meprobamate on limbic system of the brain. *Proc. Soc. Exper. Biol. Med.*, 100: 631, 1959.)

fects on some limbic structures. In rats, meprobamate sets aside the irritability and savagery on tactile stimulation following the surgical production of septal lesions. Similarly, meprobamate has been found effective in rendering the hippocampus less sensitive to stimuli, as the after-discharge following electrical stimulation of that structure is first reduced and finally eliminated (see Figure 6). This reduction of hippocampal activity may bring on an attendant diminution of anxiety.

Barbiturates. The superior effect of the psychotropic drugs, in comparison with the barbiturates, in the treatment of psychotic patients depends on the more specifically directed actions of the major tranquilizers. In vitro results on brain tissue reveal that the most profound metabolic depression produced by pentobarbital is observed on the neocortex rather than on the subcortical areas. Similarly, in vivo, the barbiturates preferentially depress the primary sensory neocortical areas, a decrease associated with the deeper depression of neocortical metabolism. Further evidence is afforded by comparative studies of the distribution of the phenothiazines and the barbiturates in the brain. Chlorpromazine is concentrated

in the neocortex to a lesser extent than in subcortical structures: hypothalamus, hippocampus, amygdala, midbrain, and medulla. In addition, chlorpromazine is found in high concentrations in the basal ganglia, thalamus, and pons. In contrast, barbiturates exhibit a nearly equal distribution in all parts of the brain.

In experimental studies of behavior, the barbiturates are less specific and extinguish both the conditioned and the unconditioned reflex responses with approximately similar dosages. The phenothiazines depress the conditioned reflex at levels significantly lower than those required for the unconditioned reflex. Thus, the barbiturates possess the more generalized actions exerted in all parts of the brain. Functionally important is the power of the barbiturates to depress significantly the mesodiencephalic activating system due to a direct action upon its caudad component, the reticular formation. These drugs, therefore, block the EEG as seen in Figure 7, as well as the behavioral elements of arousal, both of which are mediated in part by the midbrain reticular formation. Thus behavioral responses to stimuli are diminished.

The barbiturates increase the neurohormonal stores moderately. This increase, however, is secondary to central depression. Moreover, they directly diminish the excitability of the hypothalamic functions, including the center for wakefulness. In addition, the limbic structures feeding into the hypothalamus are rendered less sensitive to stimuli (see Figure 6). All these depressant actions present possible sources of the sedative-hypnotic powers of the barbiturates.

An even more significant difference between the tranquilizers in general and the barbiturates as a group is that the barbiturates exert more widespread influences on the brain, including the neocortical areas, which are associated with the so-called higher functions of the mind. For this reason, the barbiturates interfere with therapeutic processes that require understanding and cooperation, especially important with neurotic patients. In addition, in large doses, sometimes taken with suicidal intent, they present the danger of death due to respiratory failure.

Thus, the more powerful psychotropic agents, especially the phenothiazines and the iminodibenzyls, used in the treatment of psychoses, exert various actions at many sites, particularly on the structures forming the limbic cortex, a broad and varied base. This situation is analogous to the complex behavioral effects of these drugs and their successes in the management of the varied symptoms of psychotic patients. Moreover, the clinical effects seem to be specific against such psychotic manifestations as hallucinations and delusions. The minor tranquilizers, on the other hand, are found to act in comparatively fewer limbic areas and to assume an adjunctive role in the treatment of the neuroses, chiefly by their ame-

FIGURE 7. Blocking action of drugs. A, EEG alerting in response to touch is entirely eliminated by sodium Amytal as the reticular formation is inhibited. B, limbic-lobe seizures resulting from stimulation of the fornix were eliminated by pentobarbital. The blocking actions of pentobarbital on seizures were confined to the limbic lobe. Recordings were taken from median suprasylvian (MSS), sensory cortex (SC), entorhinal cortex (ENTO), hippocampus (HIPP), amygdala (AMYG), septum (SEPT), caudate nucleus (CN), and reticular formation of the mesencephalon (RF). (A, From Himwich, H. E. Tranquilizers, barbiturates and the brain. *J. Neuropsychiat*, 3: 279, 1962. B, From Killam, E. K., and Killam, K. F. The influence of drugs on central afferent pathways. In *Brain Mechanisms and Drug Actions*, W. S. Fields, editor, p. 71. Charles C Thomas, Springfield, Ill., 1957.)

literation of the anxiety associated with the neurotic processes.

The more potent major tranquilizers, used in the treatment of the psychoses, also present stronger and more frequent side reactions. The minor tranquilizers, employed with neurotic patients, exhibit fewer and milder side effects.

When the psychotropic drugs as a group are compared with the barbiturates, both at the basic and clinical levels, it is seen that the actions of the psychotropic group are more specifically directed in the treatment of mentally disturbed patients than those of the barbiturates.

Hallucinogens

Manifestations

Catechol and indole groups. The actions of psychotomimetic drugs belonging to the catechol or indole groups have been studied in controls and in former opiate addicts and psychotic patients, chiefly schizophrenics, by Harris Isbell and associates. Though behavioral alterations vary from person to person and even in a given individual, they are apt to include anxiety and difficulties in explaining sensations, in concentrating, and in understanding; all of these alterations are accompanied by flights of ideas. Elation is more common than depression. Perceptual alterations are many. Greater sensitivity to touch;

hyperacusis; changes in size, color, and depth vision; elementary kalcidoscopic visual variations; and true hallucinations are seen. In addition, depersonalization is frequently observed, and the patient thinks that the size, weight, shape, and appearance of various parts of the body change. More important, when these hallucinogens are not given in excessive doses, all of these psychotic manifestations occur in a state of clear consciousness. The characteristics of the psychotic reactions appear to be within the same spheres in the addicts and in the controls.

In active schizophrenics studied by Paul Hoch, however, greater accentuation of the psychotic symptoms is observed, with more marked disorganization of thought and less awareness of reality than in the controls, as the clinical profiles of the patients became more florid.

In "burnt out" schizophrenics, visual hallucinations and disturbances of body image are also observed. But emotional apathy and indifference appear to a greater degree in them than in patients with more active symptoms. This difference suggests a phenomenon observed with schizophrenic patients receiving monoamine oxidase inhibitors with either methionine, tryptophan, or cysteine: the symptoms characteristic of a given schizophrenic patient are repeated in more exaggerated forms during the behavioral exacerbations brought on by these treatments.

PSYCHOTOMIMETIC & NON-PSYCHOTOMIMETIC CONGENERS

FIGURE 8. Psychotomimetic and nonpsychotomimetic congeners. Note that the indole psychotomimetics have either an *N*-dimethyl group (psilocin, *N*-dimethyltryptamine) or an *N*-diethyl group (LSD), but mescaline possesses *O*-methyl groups, and nonpsychotomimetic congeners are devoid of such groups. In contrast, 4-methyl- α -methyltryptamine and the other nonpsychotomimetic congeners—tryptamine and methysergide (UML, Sansert)—do not contain either *N*-dimethyl or *N*-diethyl groups, and epinephrine does not have *O*-methyl groups. (Prepared for this chapter by H. E. Himwich.)

Systemic reactions to psychotomimetic agents, studied quantitatively, reveal rises in rectal temperature, pulse rate, respiratory rate, systolic blood pressure, and pupillary diameter. In accordance with these signs of excitation, there is also a decreased threshold for the knee jerk.

Cholinolytics. In another group of drugs, including atropine and similar cholinolytics, are two agents, scopolamine and Ditrane, an *N*-methyl-3-piperidylbenzilate studied by Abood and Meduna in 1958. Like the catechol and indole psychotomimetics, the cholinolytics produced gross distortions of visual perceptions, hallucinations, and paranoid ideation with ideas of grandeur in some patients. Others, however, exhibited chiefly a confusional state, delirium with faulty orientation, clouding of the sensorium, and memory disturbances.

This emphasis on the delirious state suggests that cholinolytics act by different mechanisms than the indole or catechol psychotomimetics.

Tolerance. The behavioral changes with the indole and catechol psychotomimetics seem to apply somewhat more closely than those with the cholinolytics to the symptoms of schizophrenia. The action mechanism in noncholinolytic psychotomimetics develops rapidly and is evident after 3 days of drug administration, both in systemic and behavioral effects. The changes in knee jerks, blood pressure, and pupillary diameter are significantly diminished. Doses even quadruple the original do not restore the original severity of the mental changes. Tolerance is also rapidly lost, and the intensities of the reactions are fully restored 3 days after the discontinuation of lysergic acid diethylamide (LSD).

The spectrums of the objective and subjective reactions to the indoles—LSD, psilocin, and psilocybin—and to the catechol, mescaline, are strikingly similar. Because of this similarity, Isbell and coworkers suggested that all four drugs produce their effects via a common mechanism. They proceeded to test this hypothesis in studies of cross-tolerance. If the loss of sensitivity to the continued administration of LSD is called direct tolerance, then the tolerance to the subsequent administration of any other member of this group of four drugs is cross-tolerance. Isbell and colleagues demonstrated strong cross-tolerances among these drugs.

Mechanism of action. The observations on cross-tolerance reveal that both the indole and the catechol psychotomimetics must be considered in the analysis of the mechanism of action, as in the experiments performed by Himwich and collaborators. A series of observations on rabbits to study indole psychotomimetics (psilocybin, psilocin, bufotenin, *N*-dimethyltryptamine, LSD) and catechols (mescaline and dimethoxyphenylethylamine) revealed that each of these drugs is capable of exciting EEG alerting in the intact animal but not in preparations with brain stem transected just below the midbrain. Thus, a structure in the lower brain stem affords a site for EEG arousal by these two groups of psychotomimetics. Though the nonpsychotomimetic congeners of these drugs also bring on EEG alerting in an animal with intact brain, a series of transections reveal that they depend on an area in the midbrain.

Chemical structure. Another difference between the psychotomimetic and nonpsychotomimetic agents is evident in the chemical structure: the molecules of the psychotomimetic agents contain either *N*-dimethyl-(CH₃) or *N*-diethyl-(C₂H₅) groups in strategic sites, but the psychotomimetic catechols are *O*-methylated. The nonpsychotomimetics do not have either *N*-dimethyl or *O*-methyl groups (see Figure 8). The *O*-methylated catechols include mescaline and dimethoxyphenylethylamine; with the latter there is a direct connection between the screening studies of psychotomimetic drugs in rabbits and the clinical observations of Friedhoff and Van Winkle, as that compound appears in the urine of schizophrenic patients.

Limbic system changes. Experiments also disclosed changes in the limbic system of the rabbit, especially in the hippocampus, with characteristic slow theta electrical potentials accompanying the EEG arousal patterns. Investigations of Monroe and Heath have revealed the great sensitivity of the hippocampus, a sensitivity that appears to be specific, as seen in discriminative task performances of cats exposed to LSD. Stimulation of the reticular formation can evoke both EEG arousal with rapid low amplitude cortical waves and hippocampal theta rhythms, and stimulation of the posterior hippocampus can also cause EEG alerting, so it would seem that these two processes are closely related phenomena.

Biochemical changes. A biochemical description of a mechanism of action of psychotogenic agents can be suggested. Because the indole amines and catecholamines are prominently represented in the limbic system, it has been suggested that the psychotogenic substances either interfere with the metabolic processes of the indoles and catechols in the brain or take the place of normal brain constituents and evoke abnormal reactions. By either process, aberrant behavioral results may be expected. The recent discoveries of the role of indoles and catechols in the urine of schizophrenic patients add substance to such a conception.

Suggested Cross References

See the chapters on schizophrenia, the depressive reactions, the brain disorders, and mental retardation (Chapters 15, 17, 18 to 21, and 22, respectively) for information regarding the clinical features of the psychiatric disorders that are discussed in this section in relation to psychopharmacology. The clinical use of the psychoactive drugs is presented in Sections 35.1 and 35.2 in the chapter on organic treatment. For a further discussion of the hallucinogens, see Section 5.4 by Mandell and West.

2.4 SLEEP AND DREAMS

WILLIAM C. DEMENT, M.D., Ph.D.

Sleep may be briefly characterized as a readily reversible suspension of sensorimotor interaction with the environment, usually associated with recumbency and immobility. As such, it appears to interrupt wakefulness periodically in vertebrate organisms, but its presence may become difficult to establish in lower organisms and plants, where it blurs with transitory intervals of inactivity resulting from environmental influences; or in higher organisms, where it is difficult to differentiate from such borderline conditions as hibernations, anesthesia, trance, and coma.

Sleep has great practical interest for biologists and psychiatrists from several points of view: (1) it provides a basal background state against which arousal or vigilance mechanisms may be superimposed and studied; (2) it poses problems related to its seeming obligatory universality; (3) it provides the physiological background for the experience of dreaming; and (4) it has clinical implications, especially in regard to sleep disturbances and the relationship of sleep to psychopathology.

The field of sleep research has been unusually active in the last few years. As a consequence, there is no simple answer to the question, "What is sleep?" The major complication in answering this question, even from a descriptive viewpoint, is the recent finding that sleep is not one thing but at least two entirely different things. It is now generally accepted that there are two kinds of sleep, which are suffi-

FIGURE 1. EEG tracings of sleep stages. These sample tracings of a subject's brain waves were made during a single night. The recording paper was moving under the pens at one-third the standard speed, which means that the waves are somewhat pushed together. The top line shows the 10-per-second alpha waves characteristic of the "awake" EEG. Their mean amplitude is about 50 microvolts. The stage 1 tracing shows a mixture of low voltage, irregular, relatively fast waves. The stage 2 tracing shows the characteristic waxing-waning bursts of regular waves (sleep spindles) lasting 1 to 2 seconds. The frequency of the spindle waves is about 12 to 14 per second, which causes them to be somewhat blurred at this paper speed. Nonetheless, they stand out sharply from the low voltage, irregular background rhythms. A moderate amount of high voltage, slow activity waves is seen in the stage 3 tracing. Stage 4 is characterized by continuous high voltage, slow activity waves. Their frequency is about 1 per second. (From Dement, W. C. *An essay on dreams*. In *New Directions in Psychology*, vol. II. Holt, Rinehart and Winston, New York, 1965.)

ciently disparate to raise the question of whether the term "sleep" should, in fact, apply to both. Moreover, within each of these major divisions, there are variations of one sort or another. It appears that our understanding of sleep mechanisms has developed to a point where no unitary explanation will suffice for all the phenomena that have been observed.

Unfortunately, there is no standard nomenclature for the two kinds of sleep, and a bewildering array of names have been used. The single term "sleep" served to cover all eventualities, with the exception of borderline states, until 1953, when Aserinsky and Kleitman at the University of Chicago reported the occurrence of rapid eye movements in sleeping subjects. It is now known that these rapid eye movements occur during a specific state, to which the term rapid eye movement (REM) sleep has been applied by some workers. In line with this, the remainder of sleep has been designated as non-rapid eye movement (NREM) sleep. A number of other labels have been applied. For example, REM sleep is also called "dreaming sleep," "paradoxical sleep," "fast sleep," "deep sleep," and "rhombencephalic sleep." NREM sleep has been called "slow sleep," "neocortical sleep," "light sleep," and "classical sleep."

Prior to the discovery of rapid eye movements, there was no suspicion that sleep was more than one thing. In general, it was felt that organisms with complex nervous systems existed on a sort of vertical continuum of sleep and wakefulness. It was assumed that, depending on the degree of central nervous activity, the organism would shift about on this continuum, through a range extending from deep sleep to a highly alert state. Thus, sleep was essentially a uniform state, varying only in intensity or depth. A great deal of early data was derived from single observations that were generalized to include the entire sleep period, the investigator feeling no need to repeat his observations in other segments of this presumably uniform state. Furthermore, some experimental studies must have confounded the two states. In the case of total sleep deprivation, for example, the organism is being simultaneously deprived of two entirely different things.

For a variety of reasons, the probability that most observations on sleep actually dealt with NREM sleep is quite high. The current situation is somewhat analogous to a Newtonian versus an Einsteinian view of physical systems. The latter does not invalidate the former; it is, rather, an extension. If most of the information obtained on sleep prior to the discovery of rapid eye movements is assumed to apply to NREM sleep, the more recent findings on both kinds of sleep simply fill out and extend the picture.

NREM Sleep

Ordinarily, the normal adult mammal, in going to sleep, passes from wakefulness into that state now known as NREM sleep. With occasional exceptions, this process is closely associated with a marked behavioral change from movement and uprightiness to stillness and recumbency. Humans—but probably not animals—can mimic many of the gross behavioral aspects of sleep. Such things as eye closure, stillness, and regular breathing can be easily simulated. Other attributes of sleep may be brought about by relaxation and recumbency alone. Because of these factors, more penetrating measures have been utilized to establish the presence of sleep. Of these, perhaps the most widely used is the electroencephalogram (EEG), which has been particularly well studied in the human.

EEG. For all practical purposes, the electroencephalogram (EEG) defines the presence of NREM sleep in the human. Actually, a small sample of brain waves contains a highly complex mixture of amplitudes and frequencies, but certain ones usually predominate and may serve to characterize the sample. It has been possible to divide the continuum of change in EEG rhythms through wakefulness and NREM sleep into several easily recognized stages. Interestingly enough, the widest range of gross variation occurs in NREM sleep, not in wakefulness. A typical categorization is illustrated in Figure 1. These definitions are strictly valid only for the human adult. In younger age

groups, the over-all frequency spectrum of the EEG is shifted toward the slow side, and classification must be altered to take this into account.

Figure 2 shows the plots of all night recordings for three representative nights of sleep. The dark bars represent REM sleep, which is discussed below. The time spent in the various stages and their periodicity are relatively constant from night to night in human subjects. These EEG stages have been presumed to indicate the depth of sleep, with the high amplitude, slow wave phase representing the maximum depth. It should be noted that stage 4, the high voltage, slow activity period, occurs mostly in the early hours of the night.

Prolonged sleep deprivation does not change the amplitude or frequency of stage 4 patterns. If amplitude and frequency are taken as some measure of depth of sleep, no increase in depth follows even as much as 11 days of total sleep deprivation. There is every likelihood that the various predominant wave patterns of these stages are produced by specific neural mechanisms and remain constant in their form, unless the mechanisms are altered by serious damage.

The NREM sleep EEG is not usually subdivided in other animals, with the exception of primates. For example, in the cat, the NREM sleep EEG is characterized by a combination of slow waves and spindles with little variability. It is of more than passing interest that an NREM sleep EEG is frequently seen in the cat when behavioral sleep, in the sense of recumbency, is not actually present. In most such cases, the animal is obviously not wide awake. However, some animals can apparently sleep in a sitting or standing position quite readily. These observations support findings in which a dissociation between EEG patterns and behavior has been demonstrated pharmacologically and surgically, with frank sleep or waking patterns accompanying their behavioral opposites.

Skeletal muscular activity. Sleep has always been considered a time of muscular relaxation in the service of rest and restoration, and in almost all cases a recumbent position is assumed. In humans, a deliberate reduction of muscular activity always precedes sleep.

In NREM sleep, there is immobility, and muscular tension in the usual sense is not present. However, if electromyographic (EMG) recordings are taken, one finds that EMG potentials continue to be present in a tonic fashion during NREM sleep. In addition, a number of spinal reflex responses may be readily elicited, particularly the tendon reflexes. And special conditions invariably associated with sleep are contractions, or at least resistance to forcing from inside, of anal and vesicular sphincters.

A great deal of body movement is initiated during NREM sleep, but it is a moot question as to whether or not sleep is actually present, in the usual sense, during the movement. EEG tracings at these moments generally show changes suggesting transient wakefulness, but the subject is not necessarily responsive, nor

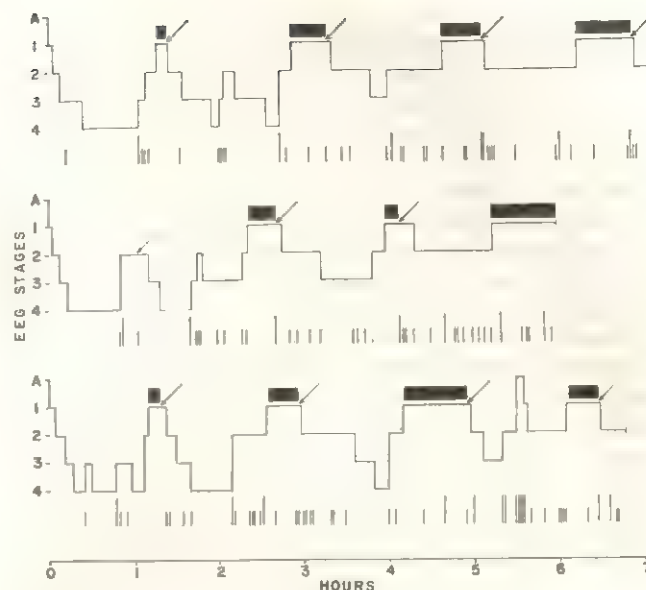

FIGURE 2. Plots of EEG stages during 3 nights. The thick bars above the EEG lines indicate periods during which rapid eye movements were seen. The arrows indicate the end of one EEG cycle and the beginning of the next. The vertical lines below each plot stand for body movements. The longer lines indicate large movement, changes in position of the whole body; the shorter lines represent smaller movements. (Reprinted by permission from Dement, W. C., and Kleitman, N. Cyclic variations in EEG during sleep and their relation to eye movements, body motility, and dreaming. *Electroenceph. Clin. Neurophysiol.*, 9: 673, 1957.)

is he likely to recall having moved. A recent study of sleepwalkers has shown that, even during actual locomotion, the brain waves do not show fully awake patterns. Thus, the sleepwalker is actually asleep, even though walking. All of this points to a diminution of motor activity during NREM sleep but no active and potent inhibition of motor functions.

Oculomotor activity. NREM sleep has its own characteristic eyeball activity, a slow, pendulous, side-to-side movement. One of the most precise indicators of some fairly abrupt transition from wakefulness to sleep, in humans at least, is the appearance of this slow oscillation of the eyes. These slow movements may occur even before there is evidence of a brain wave change. Their appearance is paralleled by a psychological alteration: the predominant mental content changes from the conceptual mode to the perceptual mode. In other words, the appearance of these eye movements correlates with the occurrence of hypnagogic imagery.

Respiratory activity. A respiratory change is often considered one of the cardinal signs of sleep. Snoring, in particular, makes the presence of sleep almost certain, unless it is being simulated. However, some investigators have found no difference in respiratory rates during NREM sleep and during quiet wakefulness. Nonetheless, in contrast to the vast repertoire of responses of the respiratory apparatus during wake-

fulness, NREM sleep is characterized by a relatively slow, regular respiratory cycle.

Of greater significance is an increase in alveolar CO_2 during sleep. This increase suggests a decrease in excitability of the respiratory center. Ventilatory response to CO_2 is found to be decreased during NREM sleep, with the decrement being proportional to the depth of sleep as measured by the EEG. The change in ventilatory response with the onset of sleep or arousal is so abrupt that a neural mechanism is strongly suggested.

Cardiovascular activity. As might be expected, heart rate is slowed during NREM sleep, although there is considerable variation from subject to subject, and blood pressure generally falls during the night. Peripheral vasodilation is closely associated with the onset of sleep. In cats, however, direct measurement of blood pressure by arterial cannulation has shown that almost no change occurs in the transition from wakefulness to NREM sleep. Using the nitrous oxide technique, one can demonstrate a statistically significant increase in cerebral blood flow; this is of theoretical importance in eliminating cerebral anemia from consideration as a cause of sleep. Cerebral oxygen uptake during NREM sleep does not appear to be changed. However, a recent investigation has shown that there is a drop in the whole organism's oxygen consumption that tends to parallel the EEG stages.

Other bodily activities. Falling body temperature, increasing basal skin resistance, and decreasing urinary output serve to distinguish NREM sleep from wakefulness. There is little evidence to support the presence of a characteristic change in the activity of the gastrointestinal tract. Spontaneous changes in basal skin potential occur much more frequently during NREM sleep stage 4 than at any other time. The basis for this autonomic hyperactivity, which is analogous to the very alert waking state, is unclear.

NREM sleep versus wakefulness. A large share of the studies of the physiological concomitants of sleep have been done on humans because their sleep is regular and predictable. However, one difficulty in attempting to assign particular significance to any physiological alteration is that many changes thought to be characteristic of sleep can be brought about merely by assuming a recumbent position.

Certainly an important feature of NREM sleep is its over-all low level of activity. Since most of our older notions about sleep as a whole are based almost exclusively on the physiology of the NREM phase, its low level of activity is responsible for the idea that the essential difference between wakefulness and sleep is the level of activity. This is unquestionably true when comparing NREM sleep to wakefulness as a whole, but it fails to take into account the tremendous repertoire of the waking state.

The main reason we think of sleep as a slowing down, a resting or idling state, is that we generally

compare it to the active waking state. The fact is that most of the changes thought to be characteristic of falling asleep are actually a result of recumbency and relaxation and can be easily achieved while still awake. If a subject lies down in a quiet room and closes his eyes and relaxes both physically and mentally, nearly every physiological measurement will show a decline in activity. The cardiac and respiratory rates will slow down, blood pressure will fall, body temperature will drop, metabolic activity will decrease. If recumbency and relaxation are maintained long enough, there may be no further change in any of these measurements when sleep finally intervenes. Accordingly, the essential difference between wakefulness and NREM sleep may not lie in the absolute level of activity in these various functions.

Interaction with the environment. The difference between wakefulness and NREM sleep may lie in the less easily quantifiable change in attentiveness and responsiveness to the outside world. Levels of activity in the waking state are usually higher than in NREM sleep because the former state is ordinarily a time of interacting with the environment. When we *voluntarily* suspend this interaction with the environment, we may achieve a low level of activity, but we are still awake. When the suspension is *involuntary*, we are asleep.

The onset of sleep is associated with a marked and abrupt change in sensorimotor function or sensory responsiveness. This change seems to be fairly accurately paralleled by EEG changes and the appearance of slow eye movements. A dramatic illustration of this parallelism has been observed in subjects whose eyes were taped open. The subjects were able to fall asleep under these conditions. While awake, they were stimulated repeatedly with a bright light, which they easily apprehended. However, at the instant the slow eye movement appeared, even before EEG changes were apparent, the bright flash of light was not consciously experienced or later recalled by the subjects. In another experiment, subjects whose eyes were taped open were stimulated intensively in all modalities and were still able to fall asleep.

Diurnal rhythm. Newborn babies show no consistent relationship of body temperature to time of day. However, within 6 to 10 weeks, there is a distinct diurnal variation, with lower body temperatures occurring at night. This cycle continues, for all practical purposes, throughout life. Its development and maintenance stem from being born into and living in a family and community run according to alterations of day and night. Nearly every visceral function, including temperature, gets pulled into the cycle.

During complete sleep deprivation in adults the 24-hour rhythms or circadian (around 24 hours) rhythms continue to occur. In studies at Walter Reed Hospital, body temperatures were recorded during sleep deprivation lasting 4 days. A diurnal variation was found that was nearly identical with that

seen during a base line period. The same sort of variation during prolonged wakefulness occurs in adrenal steroid excretion, urinary output, etc. Changes ascribed to sleep, particularly in human subjects, may be attributed to the diurnal rhythm of many bodily functions.

Summary. If one were to characterize the basic nature of NREM sleep, the definition would have to be in terms of some sort of change in the pattern of organization of cerebral activity in which there is a profound effect on sensorimotor interaction with the environment. Absolute changes in level of activity are in large part artifactual.

REM Sleep

The first hint of the dual nature of sleep came with the observation by Aserinsky and Kleitman, reported in 1953, that, during certain periods of sleep, the eyes of human subjects moved rapidly. Further studies of eye movements in conjunction with other variables established that these periods were so radically different from the remainder of sleep that the unitary concept of sleep simply would not suffice.

Electrical activity of the brain. Rapid eye movements during sleep take place within discrete intervals that are characterized by a particular EEG pattern similar to that of stage 1 (see Figure 1), a low voltage, relatively fast, mixed frequency pattern. Initially, this REM sleep pattern seemed to be identical with the NREM stage 1 pattern, which suggested that the eye movement periods represented the lightest phase of cyclic variation in depth of sleep. However, the pattern associated with REM periods actually includes saw-tooth waves that are unique to these periods (see Figure 3).

REM sleep exists throughout the family of mammals. In subhuman species, with the possible exception of the chimpanzee, the EEG during REM sleep is indistinguishable from that seen during wakefulness. Subcortical structures show unique patterns, with particular emphasis being placed on hippocampal theta rhythms seen in the cat, rat, rabbit, and (to some extent) the monkey, but not the human. This pattern is generally associated with a high degree of arousal when seen during wakefulness.

In addition, spikelike discharges appear in the pons and visual system during REM sleep. These discharges are unique to the REM period and are simultaneous with, or actually trigger, the rapid eye movements.

Oculomotor activity. Eye movements, which are one of the most striking characteristics of the REM state, are bilaterally synchronous in the human and move with a velocity that approaches or equals that exhibited during fixation shifts in the waking state. There is no particular pattern to the movement (see Figure 4), but a complex combination of all sizes and directions of arc are seen. The resemblance to purposeful waking movements is quite striking. During

FIGURE 3. REM sleep EEG patterns. These sample tracings show the saw-tooth waves that precede bursts of rapid eye movement. EEG is monopolar from the central electrode; LOC, left outer canthus to ears; ROC, right outer canthus to ears. (From Dement, W. C. Eye movements in sleep. In *The Oculomotor System*, M. Bender, editor. Hoeber Medical Division, Harper & Row, New York, 1964.)

FIGURE 4. Sample tracings of rapid eye movements showing that they are binocularly synchronous. The concomitant EEG is low voltage, nonspindling. The four eye movement pens give the left and right vertical and horizontal derivations as shown in the diagram. (Reprinted by permission from Dement, W. C. Eye movements during sleep. In *The Oculomotor System*, M. Bender, editor. Hoeber Medical Division, Harper & Row, New York, 1964.)

these movements, subjects sleeping with the eyelids taped open look uncannily awake. In the monkey, eyelid relaxation in REM sleep permits direct observation of the eyeballs; the pupils are constricted during REM sleep, and there is a certain amount of slow eye movement.

Cardiovascular activity. In human subjects, the heart rate shows a small degree of acceleration and increased variability during REM sleep as compared to adjacent periods of NREM sleep. Blood pressure rises, and finger pulse volume, which is a measure of peripheral vasoconstriction, is usually decreased.

In the cat, the heart rate is more likely to be decreased during REM sleep, and blood pressure shows a consistent drop. Cerebrocortical blood flow is markedly increased in the cat, and plethysmographic techniques indicate an increase in cerebral pulse

volume. There is also a rise in cerebral spinal fluid pressure, which suggests an increase in cerebral blood flow.

Respiratory activity. Respiration is dramatically changed during REM sleep, with an over-all acceleration and a striking increase in variability. The major volumetric change appears to be episodic shallowing, and these periods are usually associated with bursts of eye movement and a decrease in oxygen saturation of the blood. Recent studies have shown that there is an increase in oxygen utilization during REM sleep in the human.

Gastrointestinal activity. An old study by Lockhardt described the inhibition of gastric motility during periods of sleep in the dog that were characterized by twitching limb movements. Although REM sleep was unknown at the time, these twitching movements were almost certainly those that characterize this state. Studies of gastric acid secretion have shown a slight elevation in REM sleep and a dramatic elevation during REM sleep in peptic ulcer patients.

Genitourinary activity. There appears to be a decrease in urinary output during REM sleep. Of great interest are recent studies indicating that the REM period is characterized by penile erection. This has been seen in newborn infants as well as adult males. It has also been seen in cats and monkeys.

Integumentary activity. Spontaneous changes in skin resistance are decreased during REM sleep, and there is no consistent change in basal skin resistance.

Neurophysiology. Microelectrode studies on unrestrained and unanesthetized animals reveal that REM sleep is almost invariably accompanied by a marked increase in spontaneous neuronal discharge.

FIGURE 5. The onset of REM sleep. Electrode placements: ROC, right outer canthus referred to ears; LOC, left outer canthus referred to ears; EEG, left parietal electrode referred to left occipital electrode; EMG, bipolar electrodes placed on anterior neck muscles. Note that the tonic EMG potentials that were present all during NREM sleep disappear rather abruptly. A few seconds later, the first rapid eye movement potentials appear (at the right of the figure in ROC and LOC). Although it is not obvious in this brief segment of record, the EEG has changed to stage 1. (From Dement, W. C. An essay on dreams. In *New Directions in Psychology*, vol. II. Holt, Rinehart and Winston, New York, 1965.)

This increase has been seen in the visual cortex, mesencephalic reticular formation, pontine reticular formation, vestibular nuclei, lateral geniculate nuclei, and sensorimotor cortex. The discharge tends to be more paroxysmal than patterned. In addition, recent findings have shown an increase in pyramidal tract discharge.

Measurements of brain temperature indicate a substantial rise during REM sleep. There is also a marked negative shift of the transcortical DC potential. Evoked potential measurements suggest that the REM state is akin to the waking state in the handling of sensory input. There is also contraction of the middle ear muscles. When the middle ear muscles are cut, inhibition of auditory evoked potential disappears.

Muscular activity. One of the more dramatic aspects of REM sleep is the presence of peripheral twitching movements of limbs, facial muscles, etc. In dogs, particularly pets, these twitches account for the frequently described running movements that owners have inferred to be associated with dreams of chasing rabbits. However, the twitches are entirely phasic in nature, with virtually no tonic component.

An important feature of REM sleep is the presence of a tonic inhibition of motor output. Jouvet, the first to study muscular activity during REM sleep, observed the disappearance of EMG potentials (see Figure 5) and the complete abolition of decerebellate rigidity, which were present during NREM sleep. Reflex discharges are also completely suppressed. The organism during REM sleep is completely flaccid. The only muscles that maintain tonicity appear to be certain special groups, such as the extraocular muscles, middle ear muscles, and anal and vesicular sphincters.

REM sleep versus wakefulness. As the descriptive work proceeds, it is likely that any variable studied will show some kind of unique or dramatic change in association with the REM state. A question suggests itself at this point: How can we call the REM period a state of sleep or even one kind of sleep? REM sleep is very different from the ordinary conception of sleep as a state of rest, and it is very different from NREM sleep, a state of regular, low level activity. The real question, however, is: What holds the organism to its sleeping position in the face of all the central nervous activity? The probable answer is that REM sleep, in contrast to wakefulness, is a time during which a tonic inhibitory influence is brought to bear upon motor outflow. This has the effect of either attenuating or blocking the complex motor output that is elaborated at higher levels.

Temporal relationship of REM sleep and NREM sleep. Just as all mammals that have been studied show the occurrence of two kinds of sleep, they also show a characteristic cyclic alternation between the two during any lengthy period of total sleep. In the human, REM sleep interrupts NREM sleep on the

average of once every 90 minutes, lasts approximately 20 minutes, and accounts for 20 to 25 per cent of the total sleep time in young adults. In the cat, REM periods last about 7 minutes and NREM periods last about 10 to 20 minutes. In the rat, REM periods last about 1 to 2 minutes and NREM periods last about 7 to 8 minutes.

Figure 2 shows the typical sleep cycle for the adult human. NREM sleep is predominantly stage 4 in the early periods of the night, and the REM periods tend to get longer as the night wears on. This particular characteristic is more typical of humans than of other species.

The periods devoted to REM sleep and to NREM sleep vary according to age. In the immediate neonatal period in humans, REM sleep accounts for 50 per cent or more of the total time spent in sleep. Since the infant sleeps more than an adult, he experiences about four to eight times as much REM sleep as the adult. An even greater percentage of REM sleep occurs in the premature infant. This suggests that, at some point in its intrauterine existence, the human organism has nothing but REM sleep. This point of view receives support from observations on newborn kittens, in which REM sleep appears to occupy 100 per cent of the sleeping time.

In all normal adult organisms, NREM sleep generally occurs first and is then interrupted by REM sleep. Only in special circumstances do mammalian organisms go directly from wakefulness into the REM state.

Dreaming. REM sleep has also been called "dreaming sleep," for it appears to be associated with dreaming activity in a very intimate fashion. Human subjects, when awakened during REM sleep, report complex dream experiences in a high percentage of cases. In addition, the length of the REM sleep period corresponds to the length of the recalled dream. The patterns of the rapid eye movements themselves are intimately related to the visual imagery in a way that suggests the dreamer is, in fact, watching his dream. (Figure 6 shows an example of the correspondence between dream content and eye movements.) Supporting this notion are the facts that the eye movements *do* resemble purposeful waking movements and that the neurophysiological background of the REM state is compatible with a waking level of function.

However, the so-called scanning hypothesis of rapid eye movements has been called into question by a number of findings. Among these are the occurrence of rapid eye movements in newborn infants, decorated animals, and subjects who have been blind from birth. Also, the close relationship of eye movements to the pontine spike discharges, although it has not been shown in humans, suggests a different kind of mechanism. Eye movements may occur as part of a nonspecific neural activation in young or-

FIGURE 6. Example of rapid eye movement-dream imagery correspondence. After an amazingly regular sequence of 26 eye movements alternating leftward-rightward, the subject was awakened (arrow). In his dream narrative, he reported that, just prior to being aroused, he was standing at the side of a ping pong table, watching a game between two friends and looking back and forth to follow the ball. He stated that a fairly lengthy volley had just taken place. (ROC, right outer canthus monopolar electrode; LOC, left outer canthus monopolar electrode; EEG, monopolar parieto-occipital electrode. Calibrations, 1 second and 50 microvolts.) (Courtesy William C. Dement.)

ganisms that is later integrated into the total psychophysiological experience. In cats, as opposed to primates, the eye movements do not appear to resemble scanning movements; rather, they resemble nystagmoid jerks.

The problem of whether or not dreaming is exclusively confined to REM sleep seemed unimportant in the original series of studies because dream recall from awakenings during NREM sleep was at such a low level. However, more recent studies have suggested that something akin to dreaming does occur in NREM sleep, particularly at the onset of sleep, and that mental activity does take place during NREM sleep. The problem of the definition of a dream is basic to this difficulty. In general, the experiences during REM sleep appear to be more vivid, complex, emotional, and bizarre than those during NREM sleep. Recall of dreams from REM sleep seems less dependent on variables that seem to influence the incidence of recall from NREM sleep.

REM period awakenings to gather dream content from laboratory subjects have afforded considerable insight into the psychological aspects of sleep. The richness and variety of dream experience is quite impressive when the opportunity of recall is optimal. In addition, it has been shown that dream content can be influenced by external stimuli, presleep experiences, certain chemical agents, and hypnosis.

Summary. It has been suggested that, during the REM state, the brain is doing everything it would be doing if the same experience were occurring in the waking state, except that it is receiving no sensory input. In addition to an elaboration of motor output to the extraocular muscles, there are middle ear muscle contractions of a dramatic degree. And there is very likely an organized motor output to the skeletal muscles. The only thing lacking in this quasi-awake dream state is the sensory input. The endogenous elaboration of this "sensory input" is one of the mysteries of dream formation.

Mechanisms of Sleep

NREM sleep mechanism theories. In the past, sleep was thought of as a period of minimal functioning of the organism that ostensibly fulfilled a need for rest and restoration. The main problem was how this low level of function was achieved. This question now applies to NREM sleep only.

Reduction of afferent impulses. One of the most popular early theories attributed sleep to an active inhibition of nervous activity, mainly at the cortical level. However, Kleitman emphasized that sleep could also be thought of as a passive state, requiring no special mechanisms for its onset, and that the real problem was to explain the initiation and maintenance of wakefulness. He marshalled a great deal of evidence to support the hypothesis that the nervous system is maintained in a state of waking activity by the constant bombardment of afferent impulses and that the immediate cause of sleep is the reduction of afferent inflow below some critical level necessary for the waking state.

A classical experiment supporting this hypothesis was done by Bremer, who showed that transection of the brain stem at the midcollicular level, thereby depriving the forebrain of all but optic and olfactory input, immediately resulted in an uninterrupted condition of sleep, as judged by the cortical EEG and myosis of the pupils.

Normal humans prepare for sleep by imitating the effect of brain stem transection. By retiring to a quiet room, switching off the lights and radio, removing constricting clothing, lying down, and closing their eyes, they bring about a drastic reduction in afferent stimulation. In the absence of an afferent bombardment, the activity of the nervous system passively falls below some critical level, and sleep ensues.

Reduction of reticular impulses. A new twist was given to the above notion with the experiments of Moruzzi and Magoun, and subsequently many others, which showed that high frequency stimulation of the brain stem reticular formation caused EEG activation and behavioral arousal. It was also found that large lesions within the brain stem reticular formation resulted in a comatose state associated with EEG slowing that resembled changes seen during sleep. The new formulation was that the maintenance of a waking state could be attributed to a tonic barrage of ascending reticular impulses, and the steady flow of sensory messages coursing along the classical pathways appeared to be without importance for the physiology of wakefulness. The reticular activating system was conceived of as a crucial structure, interposed between the forebrain and the sensory input, that seemed to be capable of modulating or amplifying the influence of the latter. The reticular formation, particularly its mesencephalic portion, was found to receive collateral fibers from all the afferent pathways, together with centrifugal fibers from a variety of important forebrain structures. By adding

its own intrinsic activity to this multiple innervation, the reticular formation, could, it seemed, control changes in waking or sleeping behavior to some extent independent of the immediate environmental input.

Nonetheless, the essential factor producing sleep remained a passive one, except that, instead of occurring as a consequence of a reduction in direct afferent stimulation, it was the reduced number of impulses relayed by the reticular formation that allowed the activity of forebrain structures to fall below the waking level. In effect, the brain stem reticular formation became the wakefulness center.

However, many facts militate against this relatively simple hypothesis. For example, it has been shown that two stage lesioning of the reticular formation that ultimately produces a total destruction ordinarily large enough to induce perpetual coma is virtually without effect when enough recovery time is allowed between the two lesions. It has also been shown that high level brain stem transection, which effectively isolates the forebrain, is nonetheless eventually followed by the return of waking patterns in the EEG if the preparation is maintained in good condition. In addition, high frequency stimulation of many areas of the brain, including the cerebral cortex and the amygdala, has been shown to elicit arousal, although this arousal is presumed to be by centrifugal pathways to the reticular formation. And although the reticular activating system hypothesis explains the *how* of sleep, it does not explain the *why* of sleep. It is presumed that activity in the reticular formation falls partly because of neuronal fatigue. Yet this does not explain how sleep may be postponed so easily nor why it is frequently maintained so long after fatigue would be presumably reversed.

Microelectric recordings of individual neurons in the brain stem also fail to support this hypothesis. However, this evidence cannot be considered conclusive because of the small number of neurons that can be sampled. It is nonetheless true that there is apparently no decrease in rate of discharge of reticular neurons in NREM sleep versus quiet wakefulness. Prior to this, it was found that the transition from wakefulness to sleep was not necessarily accompanied by a reduction of spontaneous discharge in neuron populations in the cerebral cortex.

Neuroanatomical mechanism. A variety of studies have demonstrated that low frequency stimulation of many brain areas will precipitate the onset of EEG slowing and behavioral sleep. This is supported by evidence from our personal experience of the soporific effect of monotony. These considerations suggest the possibility of an active mechanism involved at least in the onset of sleep.

The concept of an active mechanism is not new. An early study by Nauta in the rat suggested some sort of sleep center, since destructive lesions in the ante-

rior hypothalamus seemed to result in insomnia. The work of Hess and his colleagues having to do with thalamic stimulation at low frequencies also suggested the presence of a diencephalic sleep center.

In recent years, the notion of active processes initiating sleep has been given great impetus by the work of Moruzzi and his colleagues. One of their first experiments involved the so-called midpontine pretrigeminal preparation. It was found that, immediately following a transection in this area, a larger portion of the total recording time was occupied by waking patterns in the cortical EEG. This suggested that the transection had eliminated the influence of some sleep-inducing mechanism located behind the lesion. Subsequent experiments showed that, after the basal artery had been clamped at the midpontine level, which shifted the rostral pontine region from the vertebral to the carotid blood supply, intracarotid injections of Thiopental sodium led to EEG synchronization, whereas intravertebral injections had exactly the opposite effects. This suggested that the more caudal regions of the brain stem exercised synchronizing effects on the EEG. There is a good deal of evidence that low rates of stimulation in the brain stem reticular formation and specific areas elicit EEG synchronization.

In contrast to the notion of synchronizing and sleep-inducing structures in the brain stem is the work of Jouvet on decorticate cats, from which he hypothesized that NREM sleep is actively induced by the action of the cerebral cortex. His major point is that the neocorticate cat has almost no NREM sleep but that REM sleep is virtually unimpaired. In addition, it is claimed that EEG synchronization cannot be elicited in subcortical areas by slow stimulation or barbiturates in the absence of the neocortex.

Endogenous poisoning. Although it seems that the precipitation of NREM sleep can be explained by a neural mechanism, a glance should be taken at other theories. The oldest notion with regard to sleep has to do with the idea that sleep is a result of an endogenous poisoning: certain toxins accumulate during the waking state and are eliminated during sleep. As metabolic activity eliminates the toxins, sleep ends, and wakefulness ensues. As Kleitman has pointed out, the major objection to this is that, during complete sleep deprivation, subjects almost invariably feel better and more alert the morning after a night without sleep than they did in the middle of the night.

There is no question that a variety of drugs and humoral agents can cause sleep, but there is no good evidence that sleep is associated with or dependent upon some humoral or neurochemical agent. In recent years, only the work of Monnier and Hösli supports such a mechanism.

Summary. It seems likely that the processes involved in the development of NREM sleep are complex and interrelated and probably both passive and active. The major problems lie in the establishing of a

hierarchy among the various possibilities and in separating out those effects that bear upon EEG activity alone (synchronization and desynchronization) and those that subserve behavioral wakefulness and waking performance.

REM sleep mechanisms

Neuroanatomical mechanism. Although REM sleep has been known a much shorter period of time, more definitive progress has been made in clarifying its underlying neuroanatomical substrate. In contrast to the NREM phase, REM sleep seems to depend on the integrity of a single organ located in the pontine reticular formation. There is apparently a mechanism for initiating REM sleep in this area, since lesions here seem to abolish it totally. Massive destruction of tissue elsewhere does not have this effect. It has also been shown that the motor-inhibitory process associated with REM sleep is located in this area.

Cats who had bilateral destruction of the nucleus locus coeruleus still seemed to enter the REM state. However, although certain EEG concomitants were identical with those seen in normal REM sleep, *behavioral wakefulness was retained*. This result suggests that the activity of the central nervous system during REM sleep involves elaboration of motor output, which is ordinarily prevented from reaching the periphery by a specific inhibitory mechanism. After destruction of the nucleus locus coeruleus, no such inhibition is present, and fully organized behavior patterns appear. However, the cats were totally oblivious to the environment during these "behaving" REM phases.

Biochemical mechanism. Once a REM period has occurred, another cannot be initiated or will not occur for some finite period of time. Stimulation of the brain stem in the region of the nucleus pontis caudalis may precipitate a REM period, but, once it has run its course, stimulation of this region is totally ineffective for about 15 minutes. This suggests the necessity of some sort of metabolic or biochemical buildup.

Other evidence suggesting a biochemical mechanism is the effect of drugs. Ordinarily, REM sleep is relatively constant from day to day, in contrast to NREM sleep, which seems to have the capacity to expand and contract temporally almost without limit. Certain compounds, however, will augment the amount of REM sleep, notably indole derivatives, including tryptophan, 5-hydroxytryptophan, and lysergic acid diethylamide. Monoamine compounds or compounds that effect monoamine metabolism will selectively block rapid eye movement sleep. Among these are Dexedrine, Parnate, and reserpine.

Finally, there is the curious effect of short chain fatty acids, first noted by Jouvet, who studied γ -hydroxybutyrate, and more recently reported by Matsumora and his colleagues, who studied a num-

ber of other such acids. Whether or not short chain fatty acids actually precipitate REM sleep is not certain, however, since they may simply have elicited favorable conditions for the REM-inducing mechanism.

Temperature factors. REM sleep appears to be absent in the presence of fever, and it persists or is augmented when body temperature is lowered to about 30° centigrade.

Function of Sleep

Although experimental research on sleep is extensive, and much is known, very little can yet be said about the function of sleep, either NREM or REM. Indeed, it is not certain that sleep is entirely necessary, even though we seem obliged to spend a good bit of time engaged in it.

Effects of sleep deprivation. The effects of total sleep deprivation have not been conclusive, and, as is now apparent, such studies confound the results of depriving the organism of two separate things. Since NREM sleep generally occupies the greater portion of total sleep time, the results of total sleep deprivation may reflect mainly NREM sleep deprivation.

The major effects of total sleep deprivation are an impairment of performance and the development of a tendency toward somnolence and drowsiness, of which the impaired performance may be merely a behavioral concomitant. No organic changes have been conclusively shown to be caused specifically by sleep deprivation. A major problem is keeping the organism awake long enough to demonstrate changes (if they occur) in the presence of greatly decreased motivation to stay awake plus the tendency toward somnolence. Recently a 17-year-old boy managed to stay awake for 11 consecutive days. This represented a considerable loss of NREM sleep (65 to 75 hours). When he was finally allowed to sleep, very little extra sleep occurred prior to his return to full alertness and normal performance.

The nature of NREM sleep is more consistent with notions of a state that subserves the function of rest and restoration than is the nature of REM sleep. However, crucial experiments that would demonstrate such a function are virtually impossible. There is no practical way to separate a specific effect of loss of rest from loss of sleep per se. Furthermore, the results of sleep deprivation experiments must always have the objection that one not only takes away sleep but adds an additional amount of activity, since wakefulness cannot be maintained in the absence of activity. Nonetheless, it appears that the total amount of NREM sleep can be greatly decreased without harm to the organism. The question remains as to whether or not all NREM sleep could be permanently dispensed with.

Effects of REM sleep deprivation. The function of REM sleep is possibly even less clear than that of its companion. Certainly, its physiological properties do not lend themselves to facile inferences. The high level of activity does not suggest a restorative or

resting function. However, REM sleep does have the property of behaving homeostatically and preemptively in the face of prior selective deprivation. A number of studies have shown that a certain amount of REM sleep must occur each day. If it does not occur, a deprivation effect occurs: REM sleep is made up by increasing its proportion during recovery if total sleep is held at the base line level.

The effects of prolonged selective REM sleep deprivation are somewhat surprising and seem to involve the development of neural hyperexcitability, as indicated by experiments showing enhanced auditory recovery cycle and decreased electroconvulsive seizure threshold. Nonetheless, adult animals that have been deprived of REM sleep for long periods of time do not seem drastically impaired. There has been speculation that the major function of REM sleep may be developmental, since much larger percentages are seen during the sleep of neonates and prematures. It has been suggested that REM sleep is a state that allows the developing nervous system to maintain high levels of activity and to execute or try out behavior patterns before they actually must be used in coping with the environment.

Clinical Implications¹

Sleep pathologies. There is no question that a disturbance of the mind can manifest itself in the sleeping state as well as during wakefulness. In fact, the sleeping state is often the more sensitive barometer of psychic turbulence.

Insomnia. One of the most common of all human ailments is insomnia, which is usually viewed as a symptom and assumed to be the result of some underlying anxiety, worry, conflict, or other emotional upset deriving chiefly from events in the life of the patient. There is little to do about *mild insomnia* beyond reassuring the patient, since there is no evidence that a small degree of sleep loss is harmful in any way. Naturally, it is difficult to evaluate the degree of insomnia without objective studies of sleep. The patient's description may not be an accurate portrayal. There is evidence suggesting that people who claim to be awake most of the night actually do sleep, as shown by sleep patterns in the EEG. But even when confronted with the EEG proof of sleep, they deny having slept. NREM mentation appears to be particularly intense in these subjects. Since an awareness of thinking is not compatible with their notions about the state of sleep, these people simply assume that they were awake. Another study has shown that body temperature and heart rate are chronically higher in subjects who sleep restlessly.

Severe insomnia may be viewed as a symptom of a very severe underlying disturbance. In addition, it may play a causal role either directly or as a precipitating stress.

¹ For full elaboration of these points, see Dement, W. C. *Psychophysiology of sleep and dreams*. In *American Handbook of Psychiatry*, S. Arieti, editor, vol. III, p. 290. Basic Books, New York, 1966.

Activity during sleep. Studies have been done on subjects who walk or talk in their sleep, and neither group has shown any special predilection to behave this way during REM sleep. In fact, sleepwalking tends to be initiated more frequently out of NREM stage 4 sleep early in the night, as does *pavor nocturnus*. Bed wetting in both children and adults does not appear to occur during REM sleep. In the younger group, it usually occurs during stage 4; in the older ages, it occurs in the waking state or the drowsy state. Of sleep pathologies definitely associated with REM sleep, only bruxism and rhythmic head banging have been identified.

Nightmares. These, of course, occur during REM sleep. It is quite likely that frightening dreams may precipitate a certain degree of insomnia by arousing the subject repeatedly, as may happen in the case of traumatic neurosis. One study has shown that the incidence of nightmares can be influenced by a large intake of an amino acid, tryptophan.

Idiopathic narcolepsy. This should probably be accorded the status of the pathology of sleep. It is an illness characterized by overwhelming sleep attacks, together with one or more of the following auxiliary symptoms: cataplexy, episodes of muscular weakness, usually induced by laughter or anger; sleep paralysis, attacks of inability to move, developing in the transition between arousal and sleep; and hypnagogic hallucinations, vivid visual and auditory sensations occurring at the onset of sleep.

Studies utilizing new techniques have shown that the sleep attacks of patients with narcolepsy and cataplexy are actually episodes of REM sleep. Because of the clear involvement of the REM sleep mechanism, cataplexy and sleep paralysis are viewed as the dissociated occurrence of the motor inhibitory component of REM sleep, and hypnagogic hallucinations appear to be nothing more than the vivid dreams associated with REM sleep. The essential identifying pathology in these patients is the occurrence of REM sleep at the *onset of sleep*, which never occurs in normal subjects. In a fair number of instances, cataplectic attacks have led to the development of a full blown REM episode.

Other conditions. Although not actually disorders of sleep, there are a few other illnesses in which sleep may play a role. For example, there are marked differences in epileptic seizure discharge in the various stages of sleep. Observations on the lowering of convulsive threshold associated with REM sleep deprivation suggest a causal relationship between seizures and sleep disturbances. REM deprivation in epileptic subjects may also increase seizure discharge in the EEG.

Gastric secretion during sleep in ulcer patients is markedly elevated during REM sleep and may account for the over-all elevated nocturnal secretion, which is thought to be one of the causal factors in the formation of peptic ulcer.

The cardiovascular changes during REM sleep as

well as the respiratory changes may be implicated in nocturnal disturbances in patients with hypertension, emphysema, and congestive heart failure.

Diagnostic value of disturbed sleep. Although it is a common observation that severe sleep disturbances accompany severe emotional disorders, there have been few studies in which precise correlations have been made between sleep disturbances and other measures of clinical change. One problem is that casual estimates of sleep behavior by hospital personnel are often very misleading. For example, catatonic patients may lie in bed all night with a degree of immobility that suggests deep sleep while actually not sleeping at all.

The few studies that have been done suggest that sleep disturbance has a very high correlation with clinical change. In one study, catatonic schizophrenics showed no tendency to sleep, even after being kept awake for an entire night. And in occasional cases where an acute psychosis has developed during prolonged sleep deprivation, the usual tendency to sleep has been drastically reduced.

Psychosis of sleep deprivation. Even though total sleep deprivation must have at least two separate aspects, it is possible that it is the combination of both that is psychotogenic. Recent studies of a subject who remained awake for 264 hours without showing the development of any significant psychopathology indicate, however, that psychosis is not an inevitable outcome of prolonged wakefulness. And, since 15 and 16 days of selective REM deprivation in human subjects did not precipitate a full blown psychosis in another study, it is unlikely that reported psychotogenic effects of total sleep deprivation for periods of less than 10 days were due solely to REM deprivation. It seems likely that there were predisposing factors in those cases where full blown psychosis appeared. Along this line, chronic schizophrenics deprived of all sleep for 100 hours showed a reemergence of the acute psychotic picture in every instance.

Studies of REM sleep in mental illness. Early REM deprivation studies suggested that the procedure might have an adverse effect, which led to the speculation that some abnormality of REM sleep might be associated with mental illness. In an early study, REM sleep was found to be present in a group of chronic schizophrenics, although there was no systematic attempt at quantification. More recent studies have not demonstrated dramatic quantitative differences between schizophrenics and normals. However, a significant reduction of REM time was noted in patients termed "actively ill."

Fisher and Dement studied five borderline schizophrenic patients and found a mean nightly REM time that was significantly higher than the mean for a comparable group of normals.

The finding of a high nightly REM time was confirmed in another study on a group of chronic schizophrenics in remission. Other abnormalities in this group of patients were failure to inhibit muscle potentials and an abnormal abundance of eye move-

ments in some cases. Studies of severely depressed patients have not produced consistent results.

Possible role of REM deprivation in the development of acute psychosis. An all night sleep recording will not necessarily reveal the presence of a state of REM sleep deprivation. The REM-NREM ratio obtained from an all night recording is probably the net result of many factors, the degree of REM deprivation being only one. In view of this and because of the apparent ubiquity of severe sleep disturbance in the period just prior to the full blown emergence of an acute psychosis, a possible mechanism by which interference with REM sleep may play a role has been proposed. In this formulation, it is assumed that a predisposed individual sooner or later encounters in his life experience a situation that is extremely stressful. The resultant anxiety leads to some degree of insomnia, with a disproportionate reduction in REM sleep. This situation could continue for a long time. As REM deprivation mounts, neurochemical changes in the brain increase what might be called drive pressure. In the average individual, this change might be without serious consequence, but in the schizophrenic it could be overwhelming and devastating. His weak defenses cannot cope with the greater impulsivity, the greater appetites, the hyperexcitability, etc. A vicious circle can be visualized: anxiety is heightened, which, in turn, interferes even more with REM sleep. Studies in normal subjects have shown that the effect of partial REM deprivation is cumulative for at least 20 days.

Finally, the individual reaches the point of acute psychotic disruption, generally characterized by markedly disorganized behavior, uncontrolled agitation and excitement, etc. In addition to this general effect, it is also possible that the neurochemical change induced by REM sleep deprivation may engender the formation of abnormal, possibly psychotomimetic, substances. The occurrence of abnormal compounds in the urine of schizophrenic patients and the fact that indole amines provide the nucleus for the most potent psychotomimetic compounds and also increase the amount of REM sleep support this possibility.

If this formulation is valid, it follows that the most effective way of reversing the acute psychotic state would be for REM sleep to occur. There is some evidence that phenothiazines permit the occurrence of REM sleep in acutely ill patients. Also, there is the possibility that electroconvulsive therapy causes changes in the brain that are analogous to those that occur during REM sleep.

Sleep therapy. Studies of a variety of sleep therapies have failed to show consistently favorable results in the treatment of mental disorders with this method. However, it is invariably the case that patients receiving sleep therapy are never monitored in

a way that would permit one to conclude that REM sleep has—or has not—occurred. In recent years, sleep therapy has been used sparingly, usually as an auxiliary procedure. It is obvious that the whole subject must be reevaluated in the light of recent findings pertaining to REM sleep. In view of the difficulty of precipitating REM sleep pharmacologically, it is not likely that REM sleep therapy will receive an immediate clinical trial.

Suggested Cross References

For a more complete discussion of the fundamental neuroanatomical, neurophysiological, and neurochemical topics mentioned in this section, see Sections 2.5 to 2.9, 2.10, and 2.2, respectively. In this section dreams are discussed mainly from a physiological and adaptational point of view. Dreams are discussed from a more psychodynamic viewpoint in Mack and Semrad's chapter on classical psychoanalysis (Chapter 6) in Area C, on current theories of personality and psychopathology, and in Neubauer's section on children's dreams (Section 44.3) in Area H, on child psychiatry. A discussion of the clinical use of dream material can be found in Stewart and Levine's section on psychoanalysis and psychotherapy (Section 34.1) in Area G.

Neurophysiology and Neuroanatomy

2.5 THE NEURON

ROBERT W. DOTY, Ph.D.

General Structure, Composition and Metabolism

Structure. A neuron is a cell of most peculiar shape (Figures 1 and 2). This can easily be emphasized by enlarging a Betz cell or spinal motoneuron 40,000-fold, i.e., from its actual diameter as a barely visible 50- μ speck to an irregularly shaped balloon the size of a tall man. On this enlarged scale such a neuron sends a sin-

FIGURE 1. Cells stained by Golgi method. *Left*, pyramidal cell from neocortex of a mouse, similar in configuration to Betz cells of man; *a*, basilar dendrites; *b*, apical dendrite and branches; *c*, recurrent collaterals of the axon; *e*, descending axon; *l*, white matter. *Right*, Purkinje cell from human cerebellum. Profusely branched dendritic surface accommodates up to 100,000 synapses. In all vertebrates the dendritic arborization of these cells is fan-shaped, being spread extensively in the anterior-posterior plane as viewed here from the side, and very narrow in the right-left plane. *a*, axon; *b*, axon collateral; *c*, *d*, space in which stellate cells are accommodated. (From Ramon Cajal, *S. Histologie du Système Nerveux de l'Homme et des Vertébrés*, vol. I. Translated by L. Azoulay. Consejo Superior de Investigaciones Científicas, Madrid, 1952.)

FIGURE 2. Types of neuron in brain stem and spinal cord of dog as seen with Golgi stain. *A*, reticular type of neuron; *B*, motoneuron from nucleus of seventh nerve; *C, D, E*, sensory neurons from cuneate nucleus, descending trigeminal tract and main sensory trigeminal nucleus, respectively. *a*, axons. (From Leontovich, T. A., and Zhukova, G. P. The specificity of the neuronal structure and topography of the reticular formation in the brain and spinal cord of carnivora. *J. Comp. Neurol.*, 121: 347, 1963.)

uous pipe, the axon, 0.4 m. in diameter, for up to 40 km. (from cortex into lumbar cord, or cord to foot or hand). Axons 4 km. long are common on this scale, crossing the corpus callosum or projecting to or from thalamus and cortex. A large field of repeatedly branching dendrites might extend up to 40 m. or more. Since on this scale the nerve impulse would move down such an axon at a speed of 7,000,000 km. per hour, the fiction had best be dispensed with to return to real axons which conduct at sufficiently dramatic rates from 3.6 to 360 km. per hour (1 to 120 m. per second).

The neuron's bizarre shape is dictated by two of its major functions. First, neurons provide surfaces for integrating information from diverse sources. As many as 10,000 synaptic endings may play upon one

neuron and 80 per cent of this receptive area may be provided by its dendrites. Second, the ultimate effect of this synaptic input is to generate temporally encoded digital events (impulses) which are transferred down the often prodigious lengths of the axon to form a portion of the input to still another neuron or to an effector organ.

The shape of individual neurons is revealed clearly only by the Golgi stain which in a manner wholly mysterious deposits silver throughout the entire extent of occasional cells (Figures 1 and 2). While all neurons have the same general features of soma (= perikaryon = cell body), axon, and dendrites, there are about 60 distinguishable types of neurons in mammals. Since both man and mouse have the same 60 types of neurons, a profound principle is immediately clear: the human intellect must arise from and be explicable in terms of mechanisms of neural operation common to all mammals. Wherever this principle has been tested, in the electrophysiology of the human

brain or in the functional correlates of interference with comparable neural structures in man and animals, as well as in neuroanatomy and neurochemistry, the results have been decisively consistent with this thesis of commonality among mammalian nervous systems.

Since the general functions of neurons are reflected in their shape, it is also to be expected that more subtle specializations can be discerned in the varying morphologies of the approximately 60 types of neurons. For the brain stem and spinal cord, neurons fall into three distinct morphological categories, which in turn correspond to three functional groupings (Figure 2). Neurons receiving afferent fibers from peripheral sources characteristically have short but profusely branched dendrites densely covered with "spines" (Figure 2, *C*, *D*, and *E*). Brain stem neurons of this type are thus categorized as "sensory." Electron microscopy reveals these spines to be complex structures associated with synaptic endings (Figure 3 herein, and Figure 4 in

FIG. 3. Dendritic tubules and spines in neocortex of adult cat. *A*, electron micrograph of section through a large dendrite showing prominent 230-Å diameter tubules cut at various angles. Two dendritic spines can be seen in the *upper portion* with typical synaptic ending containing synaptic vesicles apparent on the *left*. *B*, diagram of dendrite terminating in uppermost cortical neuropil (*upper left*). Diagram shows tubules extending into finest terminals, portion of elongated mitochondrion and two typical mitochondria, two multivesicular bodies, and thickening of postsynaptic membrane on dendritic trunk (1); spine (2); and terminal process (3). (From Pappas, G. D., and Purpura, D. P. Fine structure of dendrites in the superficial neocortical neuropil. *Exp. Neurol.*, 4: 507, 1961.)

Section 2.6). Motoneurons have few or no spines on their dendrites but otherwise have a large dendritic field often similar to that of sensory neurons (Figure 2B). The third category consists of "reticular" neurons which are distinguished by few, poorly ramified dendrites having large but rather sparse spines (Figure 2A). The axons of reticular neurons usually branch in a complex fashion, sending collaterals up and down the brain stem. The reticular neurons constitute the elements of the medullary and mesencephalic reticular formations, where anatomical and electrophysiological studies indicate that single cells receive afferents from many sources. Neurons of the reticular type also make up the substantia gelatinosa of Rolando, the central gray, substantia nigra, zona incerta, hypothalamus, globus pallidus, and many other nuclear groups; and in addition they are found scattered in specific sensory and other nuclei. Since units are encountered electrophysiologically which in all these structures respond "nonspecifically," i.e., to stimuli applied to two or more widely different loci, and since in sensory nuclei these nonspecific units are continuously active while those responding specifically to a single afferent source are silent until stimulated, it is possible that the reticular type of neuron will be found to have these distinctive physiological features wherever it is located.

A more certain relation between morphology and physiological characteristics is established for the basket cell system surrounding the Purkinje cells of the cerebellum or pyramidal cells of the hippocampus. In each case this dense system is the source of a deep and protracted inhibition of the Purkinje or pyramidal cells. Other opportunities abound in the visual system for identifying unique types of cells with specific physiological functions, and indeed it will no doubt ultimately be possible to infer from structure alone most of the analytical properties of a given set of neurons.

Composition. One is accustomed to thinking of the human brain with its 10 billion richly interconnected neurons (actually there are 10 billion granule cells in the cerebellum alone!) as the most complex object in the known universe. If it is possible to enhance the awesomeness of this fact, it is because each of these 10 billion units itself approaches a similar complexity in its construction. The cell body of a moderately large neuron contains 6 billion molecules of protein (assuming molecular weight = 277,000), 10 billion lipid molecules (molecular weight = 1000), perhaps 600 billion molecules of ribose nucleic acid (RNA), and 21×10^{12} potassium ions. Such a neuron is aflood with hundreds of species of complex molecules still unidentified. Beyond the overwhelming impression of mere numbers is the intricacy of the molecular framework. The RNA Nissl substance (Figure 5) constitutes about 9 per cent of the dry weight of the cell and is organized in parallel threads, suggestive of a crystalline structure, running in a continuous network of membrane-bound cavities throughout the cytoplasm but not pene-

trating axon or dendrites. This is the endoplasmic reticulum which after rupture of the neuron can be isolated as microsomes, i.e., irregularly shaped vesicles 300 to 600 Å in diameter bounded by a single 80-Å membrane, which in turn account for almost all of the neural synthesis of proteins. A second reticulum, agranular but with 100-Å membranes and 200-Å lumen, also permeates the cytoplasm and seems to correspond to the Golgi apparatus of other cells. A system of tubules is characteristic of dendrites (Figure 3) and other filaments, and tubules are found in the axon (Figure 4). The prominent nucleus, packed with deoxyribonucleic acid (DNA), is surrounded by a double membrane, and free within it is suspended a spherical mass of several thousand RNA particles, the nucleolus (Figure 5). A small nucleolar satellite of DNA, $0.5 \mu^3$, is prominent only in cells of females and bears one of the X chromosomes (Figure 5). The satellite is present in neurons of males, but it is much smaller and is seldom observed except in neurons that have been intensely stimulated. Scattered in the cytoplasm are numerous structures of unknown function such as multivesicular inclusion bodies (mostly in dendrites; Figure 3B) and granular inclusion bodies.

The mitochondrion (Figure 3) is another type of complex structure within the cytoplasm, and its intricately enfolded surfaces provide the complete metabolic machinery for obtaining usable energy from the

FIGURE 4. Neurotubules and filaments in myelinated axon in inferior olive of adult cat. Arrow points to filament, double arrow to tubule. Tubules measure 200 to 250 Å in diameter. The dark multiple lines at top and bottom are the layers of myelin. (From Walberg, F. An electron microscopic study of the inferior olive of the cat. *J. Comp. Neurol.*, 120: 1, 1963.)

FIGURE 5. Nucleolar satellite containing one of the X chromosomes as seen in motoneuron of the cat. Satellite is prominent in neurons of females only and is visible here as small dark spot just above the dark round nucleolus within the nucleus of this cell. The Nissl material containing high concentrations of RNA is seen scattered profusely within the cytoplasm. (From Barr, M. L., Bertram, L. F., and Lindsay, H. A. The morphology of the nerve cell nucleus, according to sex. *Anat. Rec.*, 107: 283, 1950.)

TABLE I

Distribution of ¹⁴C 22 Minutes after Subcutaneous Injection*

	Specific activity	Per-centage as Glucose	Percentage as Lactic, Pyruvic, and Tricarboxylic Acid Cycle Inter-mediates	Per-centage Amino Acids	Percentage of Aspartate and Glutamate in Amino Acid Content

* From Gaitonde, M. K., Marchi, S. A., and Richter, D. The utilization of glucose in the brain and other organs of the cat. *Proc. Roy. Soc. London., Ser. B*, 160: 124, 1964.

oxidation of glucose. The intense metabolic activity of neurons is reflected in the great numbers of mitochondria found in them. From presently available measurements it seems that neurons have a greater percentage of their mass devoted to mitochondria than any other cell in the body, half again as much as liver cells, the nearest contenders. Mitochondria make up about 66 per cent of the dry weight of the neuron and average roughly 1,500 per cell. Maintenance of a sta-

ble intracellular environment despite an enormous surface area for exchange with extracellular fluids places an extraordinary metabolic demand upon neurons. An indication of this is seen in the fact that as neurons mature after birth, adding greatly to their surface area by growth of dendrites, 64 per cent of the new protein formed goes into mitochondria.

Metabolism. From measurements on Betz cells isolated from the precruciate cortex of cats it can be estimated that each mitochondrion can process about 10 atoms of oxygen each microsecond. Almost all of this oxygen goes to burn glucose. Accounting in man for about 2 per cent of the body weight, the brain takes about one fourth of the total blood flow and removes proportionately more oxygen from the blood than any other organ in a resting state. Venous blood from the brain is only about 62 per cent saturated with oxygen and there is a continuous anaerobic metabolism producing lactic acid even during normal circulation. Within 22 minutes after subcutaneous injection of ¹⁴C-glucose into cats the cerebral cortex contains almost double the specific ¹⁴C activity of the heart. A large proportion of the glucose has already passed into the glycolytic and tricarboxylic acid metabolic pathways, and, in striking contrast to other tissues, over 70 per cent of the glucose has been converted into amino acids (Table I). The amino acid metabolic system of brain is highly developed and unique in its capacity to produce γ -aminobutyric acid. It is significant that about 80 per cent of the amino acids produced are glutamic and aspartic acids, both of which appear to be involved in some aspect of synaptic excitation of neurons.

Neurons versus Glia

All estimates agree that glial cells are several times more numerous in brain than are neurons. Efforts to understand cerebral function must thus face this fact and cope with the frequent suggestions that glial rather than neural activity underlies or is importantly related to mental phenomena or memory. All evidence so far strongly suggests that the glia perform mere ancillary service to supply the highly specialized environment required for neural function and that the latter is the *sine qua non* of mental life. Only neurons have the form and facility for transmitting information from and to the external world with millisecond timing and thus unquestionably serve as the afferent and efferent portals of the mind. Only neurons have the interconnectivity and demonstrable capability for rapid computation of integrated outputs derived from multiple and hence distant sources, i.e., from other brain loci. Consciousness is so fragile a phenomenon that 10 seconds without oxygen erases it, and only neurons have the intense metabolism expected to be associated with this phenomenon. Finally, RNA is associated with the manufacture of protein in accordance with phylogenetic engrams, the genetic code, and is thus at least an a priori candidate for a role in onto-

genetic engrams; and, again, only neurons have the extraordinary RNA metabolism likely to be associated with such function. Neurons thus meet all the major known requirements for correlation with mental processes, and glia do not. Assumptions, then, that important aspects of mental function are held in glia at least one step removed from neurons are thus, to say the least, gratuitous.

Types of glia. There are three types of glia: astroglia, microglia, and oligodendroglia. The astroglia weave a continuous sheet of cytoplasm into all interstices about the neurons and interpose themselves between the neurons and blood vessels. They thus appear to serve as regulators of the ionic environment of the neurons and their rather vacant appearing cytoplasm is consistent with this concept. The microglia are of mesodermal origin; i.e., they arise embryologically from non-neural tissue. Since they appear in great numbers at points of infection or degeneration, it is felt that their function may be primarily phagocytic. The oligodendroglia are more interesting. They are similar to the Schwann cells which form tubes around peripheral nerve fibers and which secrete the fatty insulating substance, myelin. Certain oligodendroglia probably perform similar functions in the central nervous system. Others undergo changes in metabolism consequent to changes in the neurons with which they are associated, and neurons of Clarke's column (nucleus dorsalis of the spinal cord) have proportionately more oligodendroglia around them the longer their axon. The oligodendroglia thus may serve as a metabolic reserve system for the neurons. From measures of glia in tissue culture, tumors, or fiber tracts (e.g., corpus callosum) their metabolism seems to be only 0.1 to 0.25 that of neurons, with the oligodendroglia having the highest rate. Thus, despite their large numbers, glia probably account for only a small proportion, 5 to 15 per cent, of the total metabolism of the brain.

Astroglia and oligodendroglia undergo periodic, sometimes rhythmical contraction in tissue culture. Such contractions, commonly lasting about 2 minutes and requiring 7 to 13 minutes for relaxation, can be triggered by electrical stimuli. The contraction is in this case preceded by an electrical response lasting 4 to 6 seconds. Neither the electrical response nor contraction is "all or none" in nature. Since similar electrical responses can be obtained in the intact brain, there is some possibility the contractile phenomena may also be characteristic of glia under normal circumstances as well as in tissue culture.

Neurons as Secretory Cells, and the Relation of Their Secretion to Their Function

In their possession of a prominent nucleolus, endoplasmic reticulum, and high levels of RNA, neurons closely resemble other cells capable of intense secretory activity such as those of the pancreas or salivary glands. Secretory activity is clearly evident in many neurons of the hypothalamus which manufacture hormones subsequently transferred to the hypophysis. All neurons, however, at their termination, seem to produce particles which are extruded onto other cells. These particles are the synaptic vesicles (Figure 3) which analyses show to be associated with synaptic transmitters such as acetylcholine or noradrenaline. There is every reason to believe that synaptic transmission is effected by the sudden release of groups of these particles from the presynaptic terminals and that a sporadic, low level release of individual vesicles is occurring at all times. It will be the thesis of this sec-

tion that, in addition to or in association with the transmitter substances, other chemical agents pass continually between neurons and are necessary to establish and maintain neural interconnections. In this view the secretory activity of neurons is thus related directly to their function, both in supplying the abrupt transients for synaptic transmission and in determining which neuron will accept or supply synapses from or to which others.

Since the microscopic structure of the nervous system can so far be viewed only in fixed preparations, the impression is easily gained that its organization is static. Living mammalian neurons in tissue culture, however, are in continual motion, sending out and retracting pseudopodia, forming synapses which remain for days or months but move about over a limited range on the surface of the contacted neurons. There is organized cytoplasmic streaming, and particles can be seen passing in persistent directions either up or down the axon. Material is transferred from nucleus or nucleolus to cytoplasm, particularly when the neuron is stimulated. The neurons produce slow, pumping movements, taking 6 to 8 hours in a cycle of contraction and expansion and seeming to effect thereby an extrusion of cytoplasm down the axon. The presence of surprisingly normal electron microscopic, histological, and electrophysiological characteristics in such explanted neurons strongly suggests that similar motility may be a common feature of neurons in their normal environment.

That axons in the mammalian central nervous system are capable of changing their connections is shown in the following experiments.

In the first stage several dorsal roots on one side are cut both rostral and caudal to a single surviving dorsal root. During the course of several months the terminals of the cut roots die and disappear, leaving a "clear" field to the single surviving dorsal root. That this root sends new terminal fibers into the fields formerly innervated by its neighbors is now shown by cutting it and comparing the zone of degeneration of this root on the deafferented side with that of the corresponding root on the other, intact side. It is found that the degeneration on the deafferented side extends in the dorsal and ventral horns several segments beyond that on the "intact" side. A similar extension of the normal innervation zone of dorsal root fibers follows partial deafferentation by extirpation of neocortex or section of a pyramidal tract. Physiological changes accompanying these deafferentations are concordant with the histological results and offer some basis for explaining certain pathological responses which follow such lesions in man.

Aside from the physiological demonstration that these enlarged central innervation zones can produce functioning synapses, little is known about the pattern, type, or stability of these new connections. In peripheral autonomic ganglia the situation is more favorable for analysis. Experiments show not only the "probing" of fibers to form new connections as "vacancies" occur in the synaptic surface of neighboring cells, but a subtle coding which selects the connections which will be most enduring (Figure 6). The cervical sympathetic ganglion receives its preganglionic fibers via the thoracic ventral roots T₁ through T₇ from neurons in the anterolateral cell column of these segments. The cervical sympathetic ganglion cells give rise to postganglionic fibers which, among other things, innervate the circular muscles of the iris and the smooth muscle

FIGURE 6. *A*, Stimulation of root at T₁ produces pupillary dilatation and at T₄, decreased ear temperature. *B*, After degeneration of T₁ fibers, T₄ fibers have grown onto cells with synaptic vacancies and stimulation at T₄ now produces pupillary dilatation as well as decrease of ear temperature. *C*, In-growing T₁ fibers select type of neurons they formerly innervated and displace T₄ fibers from them, thus restoring normal specificity of functional connections. (Adapted from Guth, L., and Bernstein, J. J. Selectivity in the re-establishment of synapses in the superior cervical sympathetic ganglion of the cat. *Exp. Neurol.*, 4: 59, 1961.)

of arterioles in the ear, producing pupillary dilation, and a fall in skin temperature of the ear as a consequence of arteriolar constriction. In the cat stimulation of the T₁ root normally produces pupillary dilation without affecting ear temperature while that at T₄ does the reverse; i.e., the fibers from these two roots go to different populations of ganglion cells. If the T₁ (and T₂-T₃) fibers are crushed, the fibers from T₄ expand their innervation zone so that, 1 month after the crushing, stimulation of the T₄ root produces pupillary dilation as well as decrease of ear temperature. Yet after 6 months, when the T₁ fibers have grown back into the ganglion, the normal situation is found to be restored. These facts provide strong *prima facie* evidence that the fibers normally innervating ganglion cells going to the ear send out collateral sprouts to form functional connections with those supplying the iris, and that these "strange" connections recede following reestablishment of contact of these ganglion cells by the fibers formerly innervating them. It also demonstrates considerable precision in the ultimate organization of cellular interconnections despite the potentiality for more diffuse, yet functional, synaptic relations.

A third example of changing neural connection is found in the visual cortex of kittens. When examined in the first weeks of life, prior to any visual experience of the animal, about 80 per cent of the cells in area striata can be influenced by stimuli to either eye; and this situation is normally maintained throughout life. However, if the animal is prevented from

using one eye for several months by suturing the eyelids together, or even if it is merely prevented from using the two eyes concurrently because of a divergence of 20° in the optical axes produced by section of a medial rectus muscle, only 5 to 20 per cent of the cells have significant binocular input. This recession of previously effective synapses in the absence of concurrent action suggests that at least in this stage of life there is some competition for synaptic space upon particular neurons and that the normal pattern of innervation represents a dynamic balance rather than a fixed arrangement.

These abnormalities of the kitten visual system become permanent as measured both electrophysiologically and behaviorally. A kitten raised without vision in either eye has difficulty learning to see but is ultimately able to do so. In the case of monocular deprivation, however, the normal eye becomes so dominant that the animal apparently can never learn to use the deprived eye. A similar permanence is achieved if vision is normal throughout the 1st year of life, for it appears that these abnormalities of binocular vision cannot be produced if the procedures are carried out on adult cats.

Effects on postsynaptic structures. Despite the presence of a "critical period" in the last instance it is clearly possible from all the foregoing to hypothesize that certain neurons in the central nervous system are continually sending out collateral, probing fibers which may establish temporary liaison with a variety of other neurons but which can maintain enduring connections only where the chemistries or activities of the two cells mesh appropriately.

In many cases it can be inferred that fibers secrete some material essential to the nutrition of the neurons they innervate since the neurons degenerate or even die following denervation.

Of course, it is possible that the denervation produces degeneration from lack of stimulation rather than from lack of a secreted neural substance. That this is not entirely the case is shown again by relations in the visual system. Within a year after section of the optic tract or loss of an eye in primates neurons of the lateral geniculate nucleus have degenerated to the point where they have lost up to 80 per cent of their normal volume. Yet in man mere lack of activity in lateral geniculate neurons of many months standing, as evidenced by blindness and caused by pressure on the optic chiasm from a pituitary adenoma, does not produce serious degeneration, since vision returns within hours after relief of the pressure. Similarly in the adult cat maintenance in total darkness for 17 months does not produce a decrease in efficacy of the postsynaptic response of the large cell system of the lateral geniculate nucleus. This lack of effect might arise because darkness is a stimulus to certain elements of the visual system, but when the dark activity is presumably removed by destruction of the photoreceptors (leaving retinal ganglion cells intact), the effect is not degeneration but increased functional capacity of the system as tested by the postsynaptic response to electrical stimulation of the optic tract.

The trophic effect of neurons upon peripheral structures is even more striking. Sensory neurons induce the formation of taste buds in the tongue and motoneurons induce motor end plates on muscle fibers. In the nictitating membrane of the cat, normally innervated by adrenergic postganglionic fibers from the cervical sympathetic ganglion, the hypoglossal nerve is able to form functional endings which are cholinergic in nature. For skeletal muscle the presence or absence of innervation effects changes in metabolism and functional characteristics throughout the entire muscle fiber. For instance, in the normally innervated fiber, microjets of acetylcholine solutions directed at the surface of the fiber elicit electrical responses only in the region of the end plate, but in denervated fibers

their entire surface becomes sensitive to such application. Within a few days after reinnervation the sensitivity recedes to be limited again to the end plate region. De-efferented muscle fibers also consistently show fibrillation, i.e., arrhythmic, brief contractions at 1 to 30 per second.

The duration of contraction in response to an electrical stimulus is slowed in de-efferented muscle, particularly in those muscles normally participating in rapid, phasic movements as contrasted to the protracted (tonic) contractions necessary for maintenance of posture. This phenomenon has been particularly well studied in the hind leg of the cat where it is found that the slow, "postural" muscles are innervated by a population of motoneurons whose electrophysiological characteristics are distinctly different from those innervating the fast, "phasic" muscles. Motoneurons to slow muscles tend to fire at low frequencies, e.g., 10 per second, but in long sustained periods of activity, whereas those to fast muscles more commonly fire in briefer bursts at higher frequencies (30 per second). In a single twitch the slow muscles normally take 60 to 80 milliseconds to reach their peak of contraction whereas a time of 25 milliseconds is typical of a fast muscle. Within a few weeks after denervation these figures change to 75 to 100 and 45 milliseconds, respectively. Within a few days after reinnervation these values approach the normal range. More interesting still, if the innervation to a fast muscle is directed onto a slow muscle, contraction of the slow muscle becomes much faster, falling to about 40 milliseconds, and the reverse occurs with fast muscles innervated by nerves normally supplying slow muscles (Figure 7). While there are some complex interactions with the amount of neuromuscular activity, which are not considered here, these experiments together with the facts cited above demonstrate that neurons exert a powerful influence upon the complex morphology, chemistry, and functional characteristics of the cells upon which they terminate.

There is every reason to believe that these effects are produced by substances secreted at the neural terminals. Furthermore, there is strong suggestive evidence that essential ingredients of this postulated secretion are manufactured in the cell body and pass continually down the axon. When an axon is severed, that portion lacking connections with the cell body disintegrates. Within 19 hours there is a detectable change in the appearance of the neural filaments, and by 1 week many fibers are only vacant tubes of myelin. The Schwann cells phagocytize the axoplasm and myelin. Conduction of nerve impulses survives for up to 3 days in the severed axon, but its failure is hastened by frequent stimulation. The fact that the axon has been severed is also somehow communicated back to the cell body, for within a matter of hours it begins to undergo drastic changes in metabolism and structure. Cell volume doubles within 5 days, apparently mostly from intake of water, and then begins a prolonged increase in number and size of mitochondria, and in proteins and RNA associated with the outgrowth of a new length of axon. The new axon is regenerated at a rate of about 4 mm. per day. To produce this rate of growth, the neuron must manufacture several times its own volume of cytoplasm each day and must do so to form ultimately a total of 50 to 1,000 times the volume of its soma, depending upon the length of the axon (0.1 to 1 m.). Motoneurons that are prevented from establishing peripheral connections frequently die after a few months, probably from "exhaustion."

Were this rate of growth a feature of normal neurons, axonal processes could move about within the central nervous system from one cell to another, i.e., grow 60 μ , the diameter of a large neuron, within 20 minutes. Evidence for the continued outgrowth of central axons is presently lacking. It is, however, firmly established that phosphoproteins move down the axons of normal motoneurons from the cell body toward the periphery at about the same 4 mm. per day seen above in the case of regeneration. The mass of material manufactured and moved is probably not nearly so great in normal neurons as in neurons regenerating axons, but it is clear that it occurs. Smaller molecules can move even more rapidly, apparently

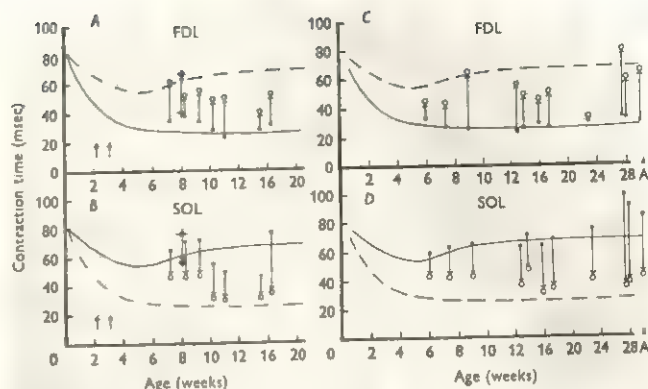

FIGURE 7. Effects of innervating soleus (SOL), a slow muscle, with nerve fibers normally going to flexor digitorum longus (FDL), a fast muscle; and vice versa. Cross union of nerves performed on kittens 16 to 22 days old (arrows) and contraction time (in milliseconds) of muscles tested at various times thereafter. The continuous lines plot the normal development of contraction time for the muscle being studied whereas the broken line plots this function for the muscle whose nerves now supply the studied muscle. In A and B the solid points are values for muscles (in contralateral limb) reinnervated by their own nerves whereas in C and D the solid points are for undisturbed, normal muscles of the animal used. Open circles in all cases indicate values for muscles receiving alien innervation, and it is obvious that these values consistently approach those expected on the basis of their innervation rather than their anatomical type. (From Buller, A. J., Eccles, J. C., and Eccles, R. M. Interactions between motoneurons and muscles in respect of the characteristic speeds of their responses. *J. Physiol.*, 160: 417, 1960.)

through rather than with the axoplasm, since phospholipids can be observed to move out of hypoglossal motoneurons along the hypoglossal nerve at 70 mm. per day.

Retrograde effects. The nature of the signal received by the cell body from the axon is unknown, and there are many unexplained factors in the phenomenon of changing cell metabolism consequent to loss of fiber terminations. For instance, such changes occur in dorsal root ganglion cells only when the peripherally projecting fibers are cut, and not when the equally long centrally projecting dorsal root fibers are cut. Cells in the thalamus degenerate within a week or two after extirpation of the neocortical area to which they project. In the rapidity with which degeneration ensues these thalamic changes are much different from those in spinal cord motoneurons following nerve section. Yet for some thalamic cells, such as those in the medial geniculate body of the cat, full degeneration is procured only by very widespread cortical removals, and loss of limited regions within this field produces little or no apparent change. This may be explained by supposing that the axons of these cells branch extensively and degeneration follows only upon removal of a certain number of these branches. The delicate trophic balance between neurons is further illustrated in cases where the degeneration proceeds transynaptically even in a retrograde direction. For instance, in both man and macaque loss of striate cortex produces degeneration in the lateral geniculate nucleus, and after several years the geniculate cells gradually die and disappear. The loss of the cells upon which they formerly terminated then also causes the retinal ganglion cells to die, even though many of them have collateral terminations in the midbrain. A similar retrograde transynaptic degeneration is seen in the medial mammillary nucleus following extirpation of the cingulate cortex in rabbits. Cells of the medial mammillary nucleus terminate in the anterior thalamic nuclei. When the cells of the anterior thalamus degenerate following loss of their cortical terminations, the terminations from the medial mammillary nucleus must also be disturbed, and de-

FIGURE 8. Photomicrograph of optic fibers transversing the area of scar tissue of cut optic nerve in a newt. A restoration of the original position of the fibers in the nerve (and ultimately in optic areas of the brain) is effected. (From Sperry, R. W. Mechanism of neural maturation. In *Handbook of Experimental Psychology*, S. S. Stevens, editor, p. 247. Wiley, New York, 1951.)

generation is then seen in the latter nucleus as well, as early as 2 weeks after the cortical loss.

It is, of course, possible or even likely that certain retrograde changes or the maintenance of a normal metabolic state requires some material that passes along the axon towards the cell body. That particles could move in axons seemed to be demonstrated for neurotropic viruses as well as by the observations in tissue culture. The viruses of herpes, rabies, and poliomyelitis move exclusively along peripheral nerves to gain access to the central nervous system. They progress at about the same rate of 2 to 4 mm. per day seen for substances moving centrifugally in the axon. The movement of these viruses, however, may be in perineural spaces rather than within axons so that until the location of the viruses can be demonstrated with the electron microscope this evidence for the centripetal movement of particulate matter within axons is not decisive.

A retrograde influence of muscle fibers upon the neurons innervating them seems necessary to explain the coordinated movements seen in supernumerary limbs grafted on salamanders. The muscles in the grafted limbs are found to contract concurrently with their homologues in the intact, normal limbs. There is no learning involved in these movements and *prima facie* it appears as though the neurons that terminate on the grafted muscles accept only those central synapses which are cognate to the type of muscle innervated. An alternative explanation is that the motoneurons send out collaterals to contact various muscles and that from the many connections so formed only those "appropriate" to each motoneuron survive, much as in the case with sympathetic preganglionic fibers in

Figure 6. Such an explanation seems to suffice for some cases, but perhaps not for all. Such selectivity in motoneuronal termination is not the case in the mammalian neuromuscular system, although nerve fibers do form more effective connections with the type of muscle previously innervated than they do with "strange" muscles. On the other hand, when nerves in the hind limbs of kittens are directed into "strange" muscles, there is good evidence that a small but significant change occurs in the central connections influencing these redirected motoneurons.

Selectivity of connections. While the case for centripetal influences of terminus back upon cell body thus remains somewhat confusing, it can be conclusively demonstrated that central fibers display an extraordinary degree of specificity in their site of termination. This can best be illustrated by examples from the visual system, although equally specific effects are obtained with vestibular or cutaneous systems. If the optic nerve is cut in fish or amphibia, the retinal ganglion cells are able to send fibers through the scar tissue along the former course of the optic tract to reestablish connections in the optic tectum. The fibers penetrate the scar in an apparent tangle of confusion (Figure 8) but then sort themselves out according to retinal locus and follow highly specific courses through the optic tract, ultimately terminating again on essentially the same cells as they did initially. There is some possibility that the final site of termination may be refined by processes analogous to those in sympathetic ganglia (Figure 6), but both behavioral and electrophysiological evidence is consistent in revealing the reestablishment of the former order. Again, learning plays no part since in a frog with eyes rotated so that its world and behavior is upside down and reversed, fibers growing in from the reversed eyes after section of the optic nerves reestablish the old connections as well as the maladaptive behavior in response to the reversed visual world. Mammalian optic nerve fibers cannot regrow in this manner, but their initial organization as to locus and type of ending are at least equally precise. Fibers from the retinal ganglion cells in the monkey sort themselves out at the chiasm into crossing and noncrossing groups and then arrange themselves within the tract according to ultimate destination in the lateral geniculate nucleus. The precision of termination carries through several stages of the system since cells found in area striata with a particular type of response to various colors of light have this same type of response to stimulation of either eye.

Maturational effects on neuron modifiability. In dealing with these concepts, care must be taken to distinguish the effects obtained in the adult, stabilized system versus those obtained in embryonic or juvenile stages.

For instance, if the eyes are rotated in amphibia sufficiently early in life, the optic nerve fibers are able to induce central changes sufficiently extensive that inverted vision and behavior does not result. In newts it is even possible in embryonic stages to remove the eyes from a species with poor vision and replace them with the larger eyes of a species having better vision. The larger eyes induce a larger optic tectum in their hosts.

As maturation proceeds, the nervous system is progressively less capable of rearrangement, and most connections ultimately seem to become immutable, all as in the situation with the kitten visual system cited above.

The stubborn fixity of these inherent, all pervasive connections cannot be overemphasized. A monkey with the flexor and extensor muscles of its arm reversed must undergo months of careful training before it is able to make even a simple, limited movement in the

sense opposite to its inherent central neural arrangement, i.e., to contract its reverse-inserted extensor muscles to produce a flexion of the arm to obtain a banana. Human patients with similar reversals have similar problems, and those with innervated skin reversed from upper to lower lips or bottom to top of finger, while able to report the proper orientation of an object touching them at these points, still continue to experience the touch as though it came at the original location of the skin. The probably small percentage of connections within the human nervous system that are modifiable can thus with effort and training be used with some success to override the effects of those which are not. The degree of modifiability, however, remains severely limited and even modified behavior requires for its expression a vast substrate of inherent connections. The gist of these pages has been that both the mutable and immutable connections are likely to arise from and be maintained by the secretory interchange between neurons.

but adequate explanation of the origin and polarity of this electrochemical potential, the resting potential of the cell, can be given wholly in terms of potassium ion concentrations. There is a high concentration of K^+ within the cell as compared with the outside, and these ions are relatively free to move through the cell membrane. The mobility of K^+ being much greater than that of the large organic anions within the cell, the tendency for outward diffusion of the positive charge (K^+) will leave the interior of the cell negative. However, if the interior of the cell is sufficiently negative, then the positive charges will be electrostatically attracted and held. An equilibrium will thus be set up where the difference in chemical concentration of K^+ inside and outside the cell is exactly balanced by the negative electrical potential holding K^+ within the cell. This potential is thus known as the "equilibrium potential," and it can be mathematically defined in terms of concentrations and mobilities for any ionic species.

If the concentration of external K^+ is increased, the resting potential diminishes according to such mathematical prediction. By this and other means it can be shown that the resting potential arises almost entirely from the difference in potassium ion concentration inside and outside the cell.

Mechanisms of K^+ - Na^+ gradient. This concentration difference is maintained by two mechanisms. Both mechanisms must operate in the face of the fact that sodium ions are present in high concentration outside the cell and are to some extent free to enter it. The first mechanism is simply the selective adsorption of K^+ rather than Na^+ by large, "fixed" anions. Thus, a muscle fiber deprived of all energy sources by anoxia, metabolic poisons, and activity to the point of exhaustion, and in a solution at $0^\circ C.$, can still adsorb K^+ and extrude Na^+ against their concentration gradients. This probably arises because the hydration diameter of K^+ is slightly smaller than that of Na^+ , thus allowing a closer approach between positive and negative charges and hence, on a statistical basis, holding K^+ more strongly than Na^+ . It is presumably this same principle of selective binding which allows potassium to be held in the soil while sodium is leached out and runs off to salt the sea. In addition to this, potassium is also accumulated inside the cell by metabolic processes. This second mechanism is known as the "sodium pump" which contributes a metabolically dependent fraction of the resting potential by actively extruding Na^+ from the cell in exchange for K^+ . Despite two decades of intensive research, the manner in which this metabolic pump operates to extrude Na^+ is still obscure.

ROBERT W. DOTY, PH.D.

Resting Potential

The interior of most cells is electrically negative with respect to the outside. Nerve and muscle cells are unique in using this difference in electrical potential as a source of energy for rapid communication from one part of the cell to the other. A simplified

Excitation

Application of electric currents through axons or other excitable tissues produces both passive and active changes. The passive changes are spoken of as "electrotonic," and their magnitude is directly proportional to the current applied (Figure 1). An electrotonic potential diminishes exponentially with distance from its point of origin. In its spread along an axon or dendrite such an electrotonic potential will be altered and slightly delayed by the electrical characteristics of these structures, i.e., by their electrical resistance and parallel capacitance along an extended surface resembling a cable.

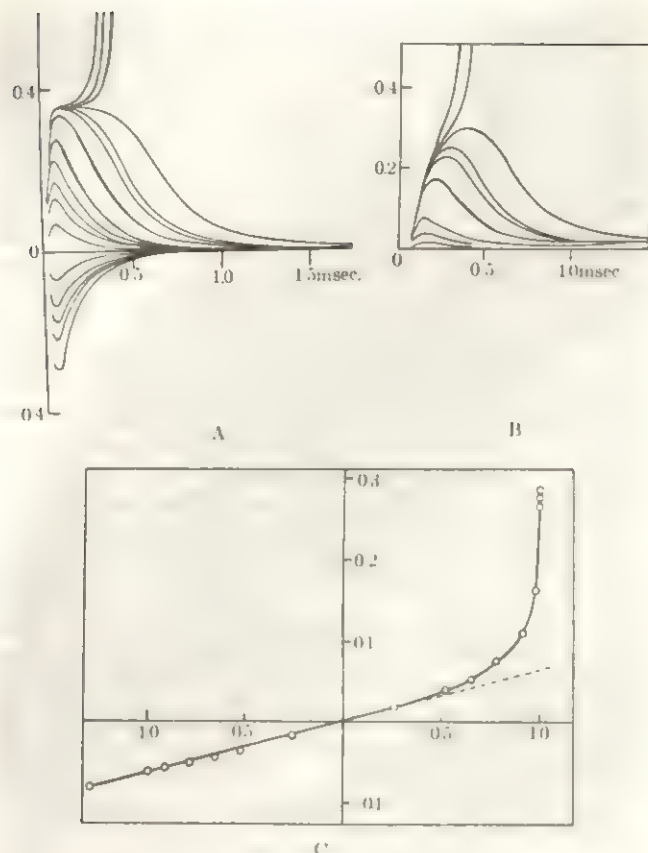

FIGURE 1. The local response of an isolated single, large axon from a crab. *A*, the responses recorded at the site of electrical stimulation. Anodal stimuli (downward deflections) produce only electrotonic potentials which are directly proportional to stimulus intensity. Cathodal stimuli (upward deflections) also produce electrotonic potentials; but with stimulus intensities half or more that required for elicitation of a propagated spike potential (uppermost lines), the response is more than a mirror image of the anodal response. This additional potential, the local response which is generated by the axon, is shown in *B*, where the electrotonic component (as determined by comparable anodal responses) has been subtracted from the records in *A*. These relations are plotted in *C* for values taken 0.29 millisecond after application of the stimulus. *Abscissa* here is the strength of stimulus as a fraction of threshold showing departure from a purely electrotonic, linear function at values about half threshold. *Ordinate* in each case is the potential as a fraction of the spike potential. (From Hodgkin, A. L. The subthreshold potentials in a crustacean nerve fiber. *Proc. Roy. Soc. London, Ser. B*, 126: 87, 1938.)

Mechanisms of excitation. Anodal current applied externally to axons merely adds to their resting potential, thus producing a hyperpolarization. This is only a passive effect without active response from the axon. The axon membrane shows some electrical rectification since externally applied cathodal currents pass more readily than do anodal currents. Cathodal current diminishes the resting potential; i.e., it acts to depolarize the axon, and the response of the axon is to add to this depolarizing effect, producing a "local response" which augments the depolarizing action and prolongs it. As more depolarizing (cathodal) current is applied, the local response becomes progressively larger (Figure 1) until at a critical level (the threshold) an explosive "all or none" change occurs which generates the nerve impulse. It is interesting that the threshold is attained by reducing the resting potential, and if the resting potential should be already lower than this critical, thresh-

old level of depolarization, the axon or cell will be inexcitable. Hyperpolarization never produces excitation but instead makes excitation more difficult the further the membrane potential is increased away from the threshold level of depolarization.

In round numbers the resting potential of a normal axon or nerve cell is about -70 mv. With depolarization to a level of about -65 to -55 mv., the membrane potential within about 0.2 millisecond reaches $+30$ mv. and then almost as abruptly begins to return to the resting level. This action is the "spike potential" associated with the nerve impulse. By changing the internal and/or external concentration of Na^+ , it can be shown that the maximum of the spike potential is the equilibrium potential for Na^+ and that during the rising phase of the spike potential most of the transmembrane current is carried by Na^+ . The spike potential thus arises from a sudden, transient change in membrane permeability to sodium ions. During the course of the spike the permeability to potassium ions also increases. The time course of this change is many times slower than that for sodium ions and the repolarization is not accomplished so rapidly as depolarization. These changes in permeability can be thought of actually as changes in conductivity which, in a manner similar to the variable resistors in an equivalent circuit, control the power drawn from the ionic concentration differences (batteries). Because of the very brief time course of the conductivity change, very little ionic movement actually occurs, most of it going simply to discharge or charge the membrane capacitance. Since these changes in sodium and potassium permeability are to a considerable degree concurrent, the ionic exchange attributable to this capacitance is 3 to 4 times that which would be expected were the changes consecutive.

The measured influx is about 3 sodium ions/100 \AA^2 of membrane surface. This influx is almost negligible in the relatively large internal volume of an axon so that thousands of impulses are required before internal ionic concentrations change significantly. With structures of smaller diameter, however, such as terminal dendrites where the surface to volume ratio may be 1,000 times greater than in axons, ionic concentrations are much more readily altered by activity.

Actually, the situation is somewhat more complicated than just described since it sometimes takes several hundred milliseconds before the resting state is fully restored. The spike potential is commonly followed first by a negative afterpotential (as recorded externally and referring to a state of transmembrane depolarization) which is relatively brief and during which a neuron may be hyperexcitable (since it would take less current to reach the threshold). An after-hyperpolarization or positive after-potential then ensues which is much longer than the negative after-potential and during which the excitability of the neuron is reduced. The positive after-potential seems to be the result of an increased permeability to potassium ions and varies greatly from one type of cell or axon to another.

Excitation increases the metabolism of axons, perhaps partly in relation to the restoration of ionic balances. In any case it has been repeatedly shown that the metabolism associated with activity is qualitatively different from that at rest.

The manner in which the sodium permeability is so abruptly and briefly altered remains unknown. The controlling systems seem to depend upon phospholipids rather than protein in the membrane. Treatment of axons with phospholipase quickly destroys their excitability, whereas the structural protein can be dissolved to the point where the nerve is a mere pulp without seriously affecting its ability to generate spike potentials. Calcium ions also play a very important role in regulating membrane permeability to sodium ions and hence control the triggering mechanism for the spike potential. The axoplasm per se plays no essential role in these events. In large axons it can be replaced with various solutions of electrolytes without altering the phenomena of excitation and conduction.

Excitation is normally initiated in axons by currents in the cell body or, in the case of afferent fibers, by currents set up in receptor structures. The latter are spoken of as "generator

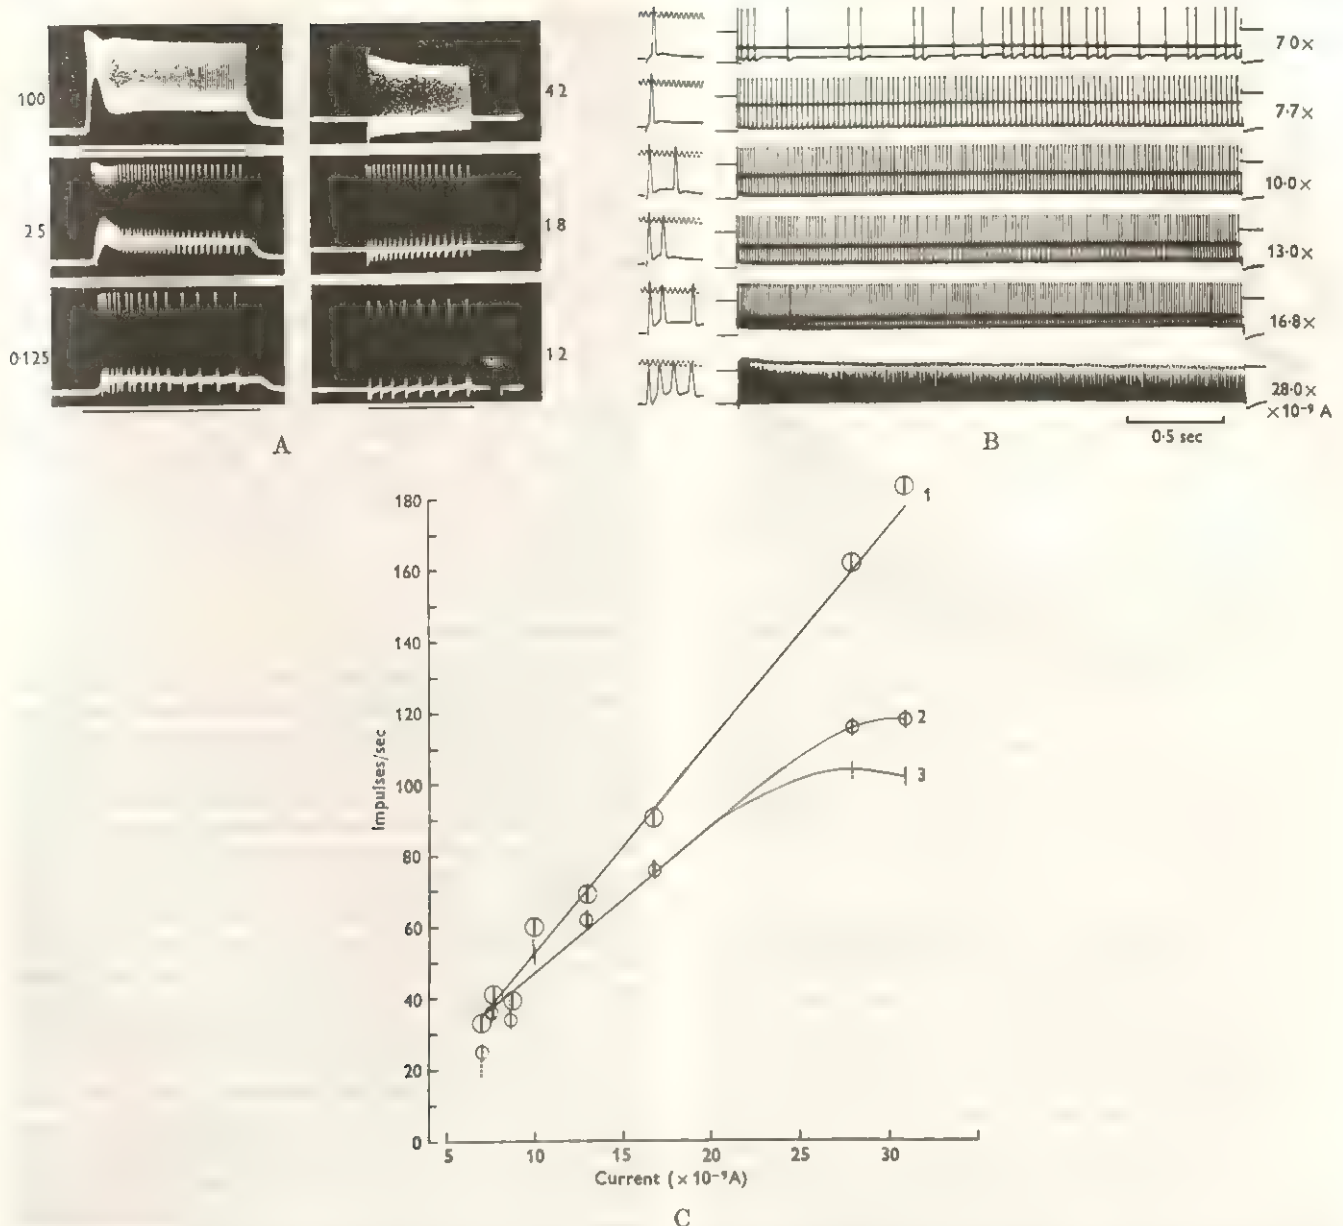

FIGURE 2. Firing frequency as a function of depolarizing currents. *A*, from eccentric cell in the eye of the horseshoe crab. At left is response to light of relative intensities, 100, 2.5, and 0.125 (flash indicated by black line beneath records). On right are similar frequencies of discharge in the same cell elicited by intracellular depolarizing currents of 4.2, 1.8, and 1.2 $\times 10^{-9}$ amp. Black line, 1 second; calibrating pulse, 20 mv. *B*, response of rat motoneuron to intracellular depolarizing currents. Rhythmic discharge occurs at 7.7×10^{-9} amp. or above, but 7.0×10^{-9} amp. merely increases rate of sporadic discharge. Records on left with 1,000 per second sine wave show responses at onset of current. *C*, relation of impulse frequency to depolarizing current for records in *B*, 1, at 0.33 second after onset; 2, at 1.3 seconds; 3, at 2.6 seconds. For curves 2 and 3 the slope constant is 4.1 impulses per second per μ amp., and for the visual cell of the crab in *A*, 4.4 impulses per second per μ amp. Such precise correlation is instructive, but fortuitous, since the cell in *A* is at room temperature and that in *B* is at 37° C. (Part *A* is from Fuortes, M. G. F. Initiation of impulses in visual cells of *Limulus*. *J. Physiol.*, 148: 14, 1959. Parts *B* and *C* are from Granit, R., Kornhuber, H. H., and Shortness, G. K. Quantitative aspects of repetitive firing of mammalian motoneurons, caused by injected currents. *J. Physiol.*, 163: 911, 1963.)

potentials" and are D.C. potentials, usually proportional to the logarithm of the stimulus energy. The effect of a steady, depolarizing potential is qualitatively similar in afferent endings or cell bodies (Figure 2), but quantitative differences are great, depending upon the characteristics of accommodation and recovery in various instances. The general effect, however, is to produce a continuing series of impulses at frequencies proportional to the intensity of the depolarizing current.

Conduction

A transmembrane current of 6×10^{-10} amp. is sufficient to excite an axon. During the spike potential the axon generates a current of about 30×10^{-10} amp. Thus there is about a 5-fold gain between the stimulating and action currents. The action current obviously will pass through adjacent regions of the axon

FIGURE 3. Myoneural junction in sartorius muscle of frog. Note complex folding of muscle membrane subjacent to the nerve ending, and presence of great numbers of particles, the synaptic vesicles, in the latter. (From Birks, R., Huxley, H. E., and Katz, B. The fine structure of the neuromuscular junction of the frog. *J. Physiol.*, 150: 134, 1960.)

and is sufficiently strong to excite them, and in this manner it produces a self-propagating spike potential. Thus, the nerve impulse is conducted successively from each point of excitation by means of eddy currents. The velocity of its propagation will depend upon how quickly the eddy currents can produce a threshold change in consecutive regions along the axon. If the external resistance is made high, as for instance by immersing a single axon in oil, the resulting restriction of current flow will slow the conduction velocity since the threshold depolarization will be reached at each new point somewhat later in the course of the action potential at the antecedent point. If, on the other hand, a shunt is provided so that the neurally generated currents can flow through a metallic conductor to a point far down the axon, the excitation will jump immediately to that distant point and thus lessen the conduction time. Both of these maneuvers, incidentally, prove the fact that it is the eddy currents which are responsible for the propagation of the nerve impulse.

A jumping or "saltation" actually occurs in vertebrate nerves, but from a channeling rather than a shunting of the currents. The fatty insulating material, myelin, present throughout the 0.4 to 1.5 mm. between nodes of Ranvier, prevents the eddy currents from entering the axon except at the nodes. Such saltation helps to increase the conduction velocity of nerve fibers, but its major advantage is probably one of con-

serving metabolic energy. It is obviously more efficient to limit the ionic exchange and resultant metabolic demands of excitation to a small area, probably about 1 per cent, of the axon rather than to involve the entire axonal surface in the process.

In intact peripheral nerves the internodal distance is proportional to the diameter of the fiber. However, when a nerve is cut and the fibers regenerate, the internodal distances are about the same for all types of fiber, yet the conduction velocity differences are still maintained. Thus, conduction velocity is a function of fiber diameter rather than internodal distance. The importance of the fiber diameter in conduction velocity arises from the fact that the longitudinal resistance of the fiber is a function of its diameter. The lower the longitudinal resistance, the more rapidly the eddy currents depolarize a node to the threshold level, and thus the more rapidly the impulse can be propagated. This emphasizes the fact that the eddy currents must flow through the axon to cause its excitation, and from this it is easy to understand how the arrangement of myelin and the random alignment of nodes between fibers renders the influence of one fiber upon another virtually nil in vertebrate nerves.

Myoneural Junction

The myoneural junction provides a conveniently accessible site for studying the transmission of excitation from one cell to another. The junction, or end plate, is a complicated structure characterized by repeated folds in the muscle membrane (Figure 3). Arrival of the nerve impulse at the axon terminal induces a 30- to 40-mv. depolarization in the muscle fiber which normally has a resting potential of about -90 mv. This depolarization is the "end plate potential" (EPP). It is several times the magnitude necessary to achieve the critical level of depolarization at which excitation becomes self-sustaining to propagate over the membrane of the muscle fiber (thus triggering the mechanical contraction of the fiber).

Chemical initiation of the end plate potential. It might be supposed that the EPP arises merely from the electrical excitation received from the axon terminal. It has, however, been conclusively shown that this is not the case but rather that the EPP arises under the influence of chemical transmitters released from the axon terminal. Indeed, many lines of evidence point to the probability that the end plate region and other subsynaptic surfaces are electrically inexcitable, i.e., that the membrane in these regions lacks the characteristics necessary for the abrupt change in sodium ion conductance needed to support a spike potential. Instead, subsynaptic membranes change their permeability only under chemical influences. A few types of invertebrate and vertebrate synapses are known in which electrical transmission does occur from one cell to another, but these instances are relatively rare.

The most critical evidence favoring chemical transmission at the myoneural junction is as follows.

The EPP endures for several milliseconds longer than the muscle spike potential, and its time course is unaffected by the discharge of an artificially induced spike potential propagating

ponderance of afferent over efferent fibers is typical of the mammalian spinal cord. The great importance of afferent inflow to the coordination of movement is seen in the fact that total deafferentation of a monkey's arm produces a condition of paralysis despite intactness of pyramidal and extrapyramidal systems. With training the animal can learn to use this arm to a limited extent, but the deficiency remains profound.

Probably the main reason for the great dependence of movement upon the afferent system is the presence of the powerful proprioceptive system coming from the muscle spindles. These spindle afferents in turn are driven by a special set of motoneurons called "gamma" motoneurons or "fusimotor" neurons which cause contraction of special muscle fibers in which the spindle receptors are embedded. By means of this fusimotor system the central nervous system initiates afferent discharge which sums with that set up by the already present state of stretch of the muscle and feeds this combined information back into the spinal cord to control the "alpha" motoneurons which produce ordinary muscular movements. Many of the afferent fibers from the muscle spindles are among the largest and fastest nerve fibers known. The intricacies of the "gamma feedback loop", i.e., the fusimotor-spindle-alpha motoneuron system, are beyond the scope of this text. It should be realized, however, that a single spindle afferent fiber forms at least four major types of connection in the spinal cord. (1) It ends directly upon motoneurons which are synergistic in their action to the muscle in which the afferent fiber originates, as well as upon motoneurons innervating surrounding portions of the originating muscle. These monosynaptic connections are excitatory. (2) It forms connections with interneurons which in turn play directly upon motoneurons supplying muscles antagonistic to that from which the spindle afferent originates. Such connections inhibit the action of the motoneurons supplying antagonistic muscles. (3) It forms powerful monosynaptic, excitatory connections within nucleus dorsalis (Clarke's column) upon the cells which project into the dorsal spinocerebellar tract. (4) It excites an interneuronal system which by multisynaptic relays comes to play upon other afferent fibers near their synaptic terminations and reduces their action by means of "presynaptic" inhibition (see below).

A motoneuron, of course, sends its axon into the ventral root; but it also sends collateral fibers into a small group of cells at the ventrocentral margin of the spinal cord gray known as "Renshaw" cells. The system of Renshaw cells produces inhibition upon motoneurons synergistic to those which supply them with collaterals. In other words, when a motoneuron discharges, it inhibits its neighbor via the Renshaw system. There is also a weak effect of inhibiting the inhibition, i.e., "disinhibition," of antagonistic motoneuronal pools.

In addition to these afferent and collateral systems there are many others driven by afferents from the joints, tendons, and skin, from contralateral as well as ipsilateral sources, together with a great variety of influences playing into the spinal cord from higher centers. Most of the current knowledge involves large cell, large fiber systems which are comparatively easy to analyze. Unfortunately, these are numerically the least important systems since there are 3 to 4 times as many unmyelinated fibers 0.3 to 1.3 μ in diameter, as there are larger myelinated fibers which range up to 12 to 20 μ in diameter.

Electrical Events in Motoneurons

Motoneurons can be impaled by microcapillary electrodes having a tip diameter of 1 to 2 μ . The entrance of the capillary tip into a neuron is signalled by an abrupt change in recorded potential from zero to about -70 mv. as the tip is advanced a few microns. Motoneurons can be unequivocally identified as such by their being excited antidromically upon stimulation of a ventral root. Similarly, in preparations with severed dorsal roots the motoneuron can be further specified exactly as to which muscle it innervates simply by finding which muscle

nerve excites it antidromically. The Renshaw cells, which are also activated by antidromic stimulation of motor axons, cannot be confused with motoneurons since their response is not of an antidromic type.

A double-barrelled microelectrode is often employed so that the membrane potential can be set electrically (by a "voltage clamp") or the internal ionic environment altered by electrophoretic injections with one barrel, while the second barrel of the electrode is used to record the reaction of the impaled cell. When by such means a motoneuron is hyperpolarized, it becomes less likely that it will be invaded by antidromic impulses. This manipulation reveals three all or none stages in the antidromic invasion of the neuron (Figure 5). The interpretation of these stages is as follows. (1) With intense hyperpolarization only a small potential, the "M" spike, is recorded in the soma. The M spike represents the distant impulse subsiding at the first myelinated segment as it fails to propagate into the hyperpolarized region. (2) With less severe hyperpolarization the antidromic invasion proceeds somewhat farther, presumably into the initial segment of the axon where it produces the "IS" spike which, however, is still remote from the recording electrode. (3) Usually at normal levels of membrane potential the cell body and probably the dendrites are invaded, giving rise to the "SD" spike which is the fully developed, all or none spike of the motoneuron *per se*. With orthodromic excitation or with excitation from intracellularly applied currents the motoneuron discharge is always initiated by a potential exactly like that of the antidromically analyzed IS spike. Hence it seems certain that excitation originates in the initial segment rather than in the soma or dendrites (Figure 5). Thus the initial segment of the axon is critical in the excitatory processes of the neuron since it has the lowest threshold and its discharge will propagate a spike both down the axon and up over the soma and into the dendrites.

The SD spike is commonly followed by delayed depolarization and/or by hyperpolarizing and finally by depolarizing after-potentials (Figure 6). The dendrites presumably make important contributions to these potentials since they are not seen following an IS spike. The delayed depolarization usually is of the order of 3 to 7 mv. on the falling phase of the SD spike and lasts 3 to 6 milliseconds (Figure 6A). The after-hyperpolarization is much more protracted, attaining about 5 mv. at 10 milliseconds and then, for motoneurons innervating fast contracting muscles, endures for about 70 to 80 milliseconds; and for motoneurons innervating slowly contracting muscles it may last 150 milliseconds. This after-hyperpolarization is independent of that produced by the Renshaw system (which has similar effects lasting about 50 milliseconds) and arises from a slight change in membrane permeability permitting a greater outward flux of potassium ions.

By stimulating the neurons directly with depolarizing currents supplied through an internal microelectrode, a number of interesting and important features are revealed. First, the form of response of the neuron is essentially identical to that which occurs to natural, orthodromic excitation (Figure 5, Part III). At a certain level of depolarizing current the neuron begins to discharge repetitively and regularly so long as the current is maintained. (Figure 2, B and C). Below this current level it merely discharges sporadically. The frequency of discharge is highest immediately after onset of a continuous current, falls slightly during an adaptation period of 0.1 to 1.0 second, and is then maintained steadily for long periods. Within the physiological range of discharge from a minimum steady rate of about 15 per second to a maximum steady rate of 50 per second the relation of the frequency to the intensity of the depolarizing current is essentially linear (Figure 2C). There is, however, a 10-fold range in the slope of this frequency-intensity relationship; i.e., some neurons will have an output 10 times greater than others for the "same" input. This means that the effectiveness of a given excitatory background upon a given neuron will depend upon the neuron's size, geometry,

locus of synapses, and other factors. The neuron's characteristics in this regard can be predicted from its after-potentials (Figure 6B). The minimal frequency of steady repetitive firing is related to the peak of the later after-depolarization and matches the frequency at which the innervated muscle is

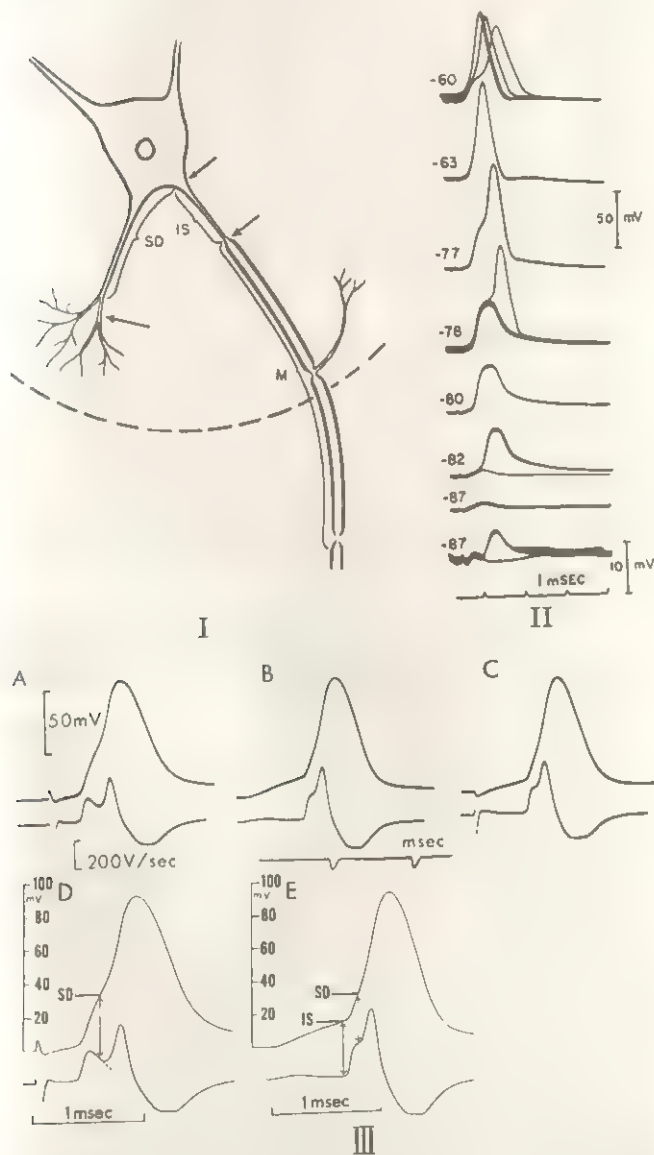

FIGURE 5. Components of potentials generated in motoneurons. I, segments of motoneuron; II, the responses obtained by antidromic stimulation when membrane potential, -80 mv. at rest in this cell, is set at different levels by intracellularly applied currents (see the text). In III a motoneuron with -70 mv. resting potential is stimulated antidromically (A, D), by a monosynaptic EPSP (B, E) and by a depolarizing intracellular pulse (C). The lower trace of each pair is an electrical differentiation showing the rate of change of potential in the upper traces, making more clear the fact that similar components are present in each case. In D and E the perpendicular lines indicate the start of the IS and SD components and the horizontal lines indicate their respective thresholds. (From Eccles, J. C. *The Physiology of Nerve Cells*. Johns Hopkins Press, Baltimore, 1957; and from Eccles, J. C. *The excitatory responses of spinal neurones*. In *Progress in Brain Research*, J. C. Eccles and J. P. Schädé, editors, vol. 12, p. 1. Elsevier, Amsterdam, 1964.)

FIGURE 6. After-potentials in motoneurons. A, from L_4 segment in rat showing delayed depolarization ("hump" following spike) and beginning after-hyperpolarization following orthodromically elicited spike. Record to right shows repeated traces with near threshold stimuli in which spike sometimes did not develop, thus providing base line of resting potential from which to judge the magnitude of the after-hyperpolarization. Calibration 20 mv. and 1,000 Hz. B, relation between minimal frequency of steady repetitive firing (e.g., at 7.7×10^{-9} amp. in Figure 3B) of cat motoneurons and reciprocal of the time to peak of after-depolarization (arrow on inset). Inset, at slow sweep speed, shows antidromic response of neuron with deep after-hyperpolarization and late after-depolarization (barely visible at this gain). (Part A is from Granit, R., Kernell, D., and Smith, R. S. Delayed depolarization and repetitive response to intracellular stimulation of mammalian motoneurons. *J. Physiol.*, 168: 890, 1963. Part B is from Kernell, D. The limits of firing frequency in cat lumbosacral motoneurons possessing different time courses of after-hyperpolarization. *Acta Physiol. Scand.*, 65: 87, 1965.)

known to begin mechanical summation of contractions. The maximum steady frequency, on the other hand, is closely related to the duration of after-hyperpolarization and in turn matches the maximum useful frequency for obtaining tetanic fusion in the innervated muscle. Thus, the temporal characteristics of neurons fit them precisely into various physiological roles, and it seems safe to assume that similar principles will hold for many other neuronal systems of the brain. For instance, it is found that interneurons in the spinal cord fire much more rapidly for a slight change of intracellular depolarizing current than do motoneurons. Interneurons should thus be well suited for "amplifying" incoming signals, and with their higher output frequencies they provide the natural "depolarizing pressure" required for sustained activity in the motoneurons.

Excitatory postsynaptic potential. A single orthodromic synchronous volley entering the dorsal roots

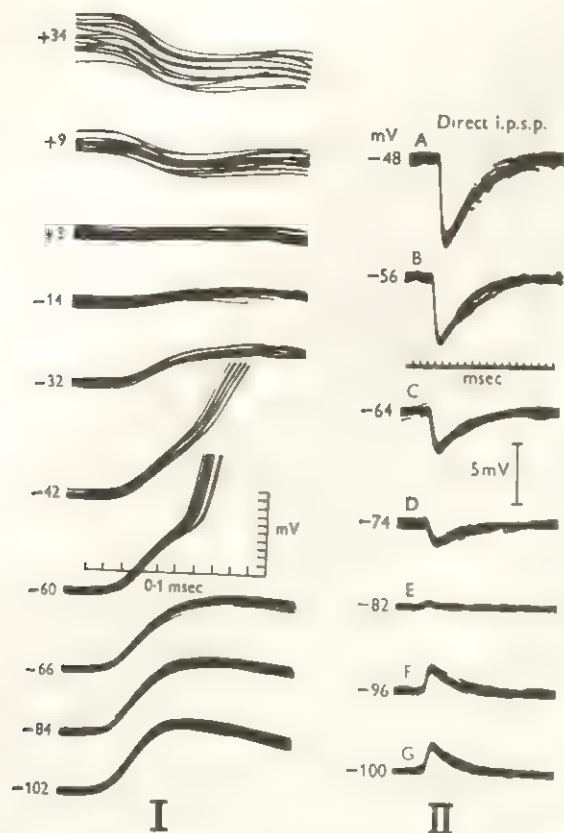

FIGURE 7. Excitatory (I) and inhibitory (II) postsynaptic potentials of cat motoneurons as modified by setting of the membrane potential at different levels. Upward deflection indicates depolarization. Membrane potential controlled through one of the two electrodes impaling the cell and its level is indicated at the left of each set of about 20 superimposed responses. I, biceps-semitendinosus motoneuron with resting potential of -66 mv. Equilibrium potential for EPSP is $\sim +3$ mv., and when membrane potential is greater than this value (e.g., $+9$ and $+34$ mv.), it also moves towards $+3$ mv. during the EPSP process. In II, a biceps-semitendinosus motoneuron with a resting potential of -74 mv. is subjected to inhibitory volleys from quadriceps afferent fibers. The equilibrium potential for the IPSP is apparently about -80 mv., and the potential moves towards this value whether depolarized (-64 , -56 , and -48 mv.) or hyperpolarized (-82 , -96 , and -100 mv.) (see the text). (Part I is from Coombs, J. S., Eccles, J. C., and Fatt, P. Excitatory synaptic action in motoneurons. *J. Physiol.*, 130: 374, 1955. Part II is from Coombs, J. S., Eccles, J. C., and Fatt, P. The specific ionic conductances and the ionic movements across the motoneuronal membrane that produce the inhibitory post-synaptic potential. *J. Physiol.*, 130: 326, 1955.)

after stimulation of an appropriate muscle nerve produces a brief depolarizing action in an impaled motoneuron. This depolarization is the excitatory postsynaptic potential (EPSP) arising from activity of afferent fibers with direct, "monosynaptic" connections to motoneurons.

The amplitude of the EPSP will depend upon how many afferent fibers are synchronously discharged, and hence the EPSP can be graded by changes in stimulus intensity. (Up to the point of exciting all fibers, the number of fibers excited in a nerve will depend upon the intensity of an electrical

stimulus.) The EPSP rises to a maximum within about 1.0 millisecond and then decays with a time constant of about 5 milliseconds (Figure 7). This rather long course of action probably results from residual transmitter action. Since a significant fraction of the depolarization continues even out to 12 milliseconds, a second EPSP induced within this time can sum with the first. The neuron discharges by initiating an IS spike when depolarization from the EPSPs reaches 5 to 18 mv.

Because spontaneous neural discharge is omnipresent in the central nervous system, it is very difficult to determine whether random "miniature EPSPs," analogous to the MEPPs at the myoneural junction, occur in the absence of presynaptic spikes. However, when all conduction is blocked in the isolated spinal cord of the frog by treating it with solutions with a high magnesium content, a background of EPSPs, many with identical amplitude, can still be recorded.

This suggests that the quantal release of transmitter occurs spontaneously at central synapses as well as at the myoneural junction (as it also does in autonomic ganglia).

Inhibitory postsynaptic potential. Brief hyperpolarizing potentials are produced in an impaled motoneuron by stimulation of nerves from muscles with action which is antagonistic to that innervated by the impaled neuron. Since hyperpolarization carries the membrane potential away from the threshold level, it has the effect of inhibiting the activity of the neuron. Hence, these potentials are termed inhibitory postsynaptic potentials (IPSPs).

The IPSPs are essentially a mirror image of the EPSPs (Figure 7), although their time course is slightly shorter. The amplitude of the IPSP also depends upon the number of fibers active in the synchronous afferent volley.

It can be inferred that the same fiber can generate EPSPs in one set of motoneurons and IPSPs in other motoneurons. These "direct" inhibitory connections, however, have a slight but significantly longer latency than the excitatory. Measuring from the time when the afferent volley enters the spinal cord over the dorsal roots until action is produced in an impaled motoneuron, it takes about 1.0 millisecond longer to evoke an IPSP than it does to evoke an EPSP. This 1.0-millisecond delay is *prima facie* evidence for the existence of an interneuron in the inhibitory pathway. The following evidence is sufficiently convincing to validate the existence of such an inhibitory interneuron. It might first be supposed that the inhibitory nerve branches were smaller than the excitatory ones as they approached their termination in the cord, or that it took a longer time to mobilize and release the inhibitory as opposed to the excitatory transmitter, thus accounting for the extra delay for the IPSP. This is not the case, however, since upon stimulation within the ventral horn, where the presynaptic fibers producing EPSPs and IPSPs can be directly stimulated, the latencies for the two processes are identical. The delay at the synaptic terminal is about 0.3 millisecond in each case. IPSPs can be produced by concurrent stimulation of two separate afferent sources where neither alone has any effect. There thus must exist remote from the motoneuron a common site (i.e., an interneuron) where such summation occurs. Finally, interneurons in the intermediate nucleus of the cord have been found that fire in appropriate relation to the timing of the IPSPs. Stimulation in this nucleus can produce IPSPs.

Ionic Basis of EPSPs and IPSPs

One of the most ingenious triumphs of neurophysiology has been the identification of the ionic events underlying the generation of EPSPs and IPSPs. This was accomplished by determining the equilibrium potentials for the IPSP and EPSP processes and then altering the intracellular concentration of various ions to determine which ionic species contributed to

these equilibrium potentials. The procedure is illustrated in Figures 7 and 8. The motoneuron is impaled with a double-barrelled microelectrode. Through one barrel of the electrode the membrane potential is "clamped" at any desired voltage level and with the other barrel the response of the neuron to excitatory and inhibitory volleys is then recorded. In Figure 7, *Part I*, at -60 mv., the excitatory volley produces an EPSP which is sufficient to attain the threshold and discharge a spike potential. This still occurs when the membrane potential is artificially set at -42 mv., but at this level the processes are slowed by the lack of adequate driving voltage. At -32 mv. the EPSP is considerably reduced, and the neuron probably could not discharge since it is being held depolarized beyond the threshold level. The equilibrium potential is seen to be about $+3$ mv. where no current flows during the EPSP since the electrical potential balances the ionic concentration differences which underlie the generation of the EPSP. When the membrane potential is set at still more positive voltages, the current actually moves in the opposite direction, towards the equilibrium potential, during the impingement of the excitatory volley. A similar analysis is shown in Figure 7, *Part II*, for an inhibitory volley producing IPSPs which, at the resting level of -74 mv., produced hyperpolarizing IPSPs. The equilibrium potential is found to be approximately 80 mv., and when the membrane potential is moved beyond this equilibrium to -96 or -100 mv. the potential change during the inhibitory action is reversed since it still moves towards the equilibrium potential.

The equilibrium potential for the SD spike is approximately $+40$ mv., which is the same as that found for the spike process of peripheral nerve. This and other evidence indicate that the process generating the SD spike changes the membrane conductance only for sodium ions. The equilibrium potential of -10 to ± 0 mv. for the EPSP is the same as for the EPP, and both appear to be generated by simultaneous changes in membrane permeability to all the major electrolytes, i.e., Na^+ , K^+ , Cl^- .

The equilibrium potential of -80 mv. for the IPSP process can be shown to arise from a change in membrane permeability to ions with a hydrated diameter similar to that of K^+ or Cl^- . The case for the participation of Cl^- is illustrated in Figure 8. The motoneuron was in this case penetrated with an electrode containing KCl. Immediately after penetration an inhibitory volley produced the usual IPSP as shown in Figure 8A. Within a short time (Figure 8, B and C), however, the gradual diffusion of Cl^- from the electrode was sufficient to produce a significant change in the intracellular concentration of Cl^- . As this occurred, the equilibrium potential of the IPSP changed, ultimately becoming less than the resting potential (-59 mv.). Thus, during the inhibitory volley the membrane potential moved towards a new equilibrium potential for the IPSP, i.e., in a depolarizing direction. When the membrane potential was artificially set at -41 mv. (Figure 8D), the inhibitory volley again produced a hyperpolarizing response as the potential still moved in the direction of the new equilibrium potential of the IPSP. Chloride ions were then deliberately injected into the cell for 1 minute by passing a current of 3.2×10^{-8} amp., electrode-negative. Following such a loading of the neuron with Cl^- , inhibitory volleys produce depolarizing potentials sufficient to attain threshold and produce an SD spike (Figure 8, E, F, and G)! During the course of about 1 minute (Figure 8, E to L), the excess chloride leaves the cell and the previous situation is restored (compare L with C, in Figure 8). Such an effect would result if the membrane became highly permeable to Cl^- during the IPSP. With a high intracellular concentration of Cl^- the equilibrium potential for Cl^- would be considerably less than the membrane resting potential and hence as the IPSP changed the permeability for Cl^- this equilibrium potential would predominate.

Anions fall into two groups: those which can and those which cannot mimic these effects of Cl^- . The distinguishing characteristic for effectiveness versus ineffectiveness in this re-

FIGURE 8. Intracellular recording, through a double-barrelled microelectrode filled with 3 M KCl , of IPSPs generated in a cat biceps-semitendinosus motoneuron by quadriceps afferent volleys. A, shortly after penetration of the cell; B and C, reversal of IPSP by diffusion of Cl^- from electrode; D, restoration of hyperpolarizing effect of IPSP when membrane potential set at -41 mv. Cl^- was then deliberately injected into the cell for 1 minute, thus changing the equilibrium potential for Cl^- to a level less than the threshold of the cell. Hence, the membrane potential moves towards this level during the IPSP and, crossing the threshold, discharges the cell (E, F, G). Diffusion gradually reduces the intracellular concentration of Cl^- (G to K), until the previous level (C) is reached (L) (see the text). (From Eccles, J. C. *The Physiology of Nerve Cells*, p. 107. Johns Hopkins Press, Baltimore, 1957.)

gard seems to be purely a function of the hydrated diameter of the ion. Only the smaller anions such as Cl^- , Br^- , NO_3^- , etc. are effective. Since K^+ and Cl^- are the only ions within this range of diameters normally present in the cell in significant amounts, it must be assumed that these are the only ions which participate in the IPSP process. Proof of the participation of K^+ in the IPSP is difficult since the intracellular concentration of K^+ is so high that it cannot easily be changed significantly. However, all evidence currently available points strongly toward the normal equilibrium potential for the IPSP being the balance between the equilibrium potentials of Cl^- (approximately -70 mv.) and K^+ (-90 mv.) to give the observed value of -80 mv. for the IPSP.

Presynaptic Inhibition

Both EPSPs and IPSPs are "postsynaptic" events; i.e., they occur in the cell upon which the afferent terminals impinge. The inhibitory action arises because the IPSPs sum with and thus reduce the magnitude of EPSPs. In "presynaptic" inhibition, which is probably a more common arrangement than postsynaptic inhibition, the magnitude of the EPSPs is also reduced, but no IPSPs ever appear in response to the inhibitory volley alone. It must thus be inferred that the inhibitory volley somehow acts directly upon the afferent fibers or the presynaptic terminals to reduce their capacity to generate EPSPs. The axoaxonic endings mentioned above are presumably the anatomical substrate for this presynaptic effect.

It had long been known electrophysiologically that certain inhibitory effects were accompanied by positive potentials at the surface of the spinal cord and in the dorsal roots. These potentials had a latency of about 5 milliseconds following the entry of an inhibitory volley into the cord, reached their maximum at

about 20 milliseconds, and usually took more than 200 milliseconds to subside. The temporal course of these potentials has now been found to coincide precisely with that of presynaptic inhibition. The relatively long latency arises apparently from multisynaptic relays in interneurons of the dorsal horn whose action is necessary for presynaptic inhibition. During the course of presynaptic inhibition the threshold for the stimulation of the inhibited afferent fibers is diminished, thus suggesting that they are partially depolarized. Direct proof of this state of depolarization has been obtained by intracellular recording from primary afferent fibers. Presynaptic inhibition is thus produced by a multineuronal circuit which partially depolarizes afferent terminals, thereby diminishing their action potentials and the consequent release of synaptic transmitter.

The pharmacology of presynaptic inhibition is distinctly different from that of postsynaptic inhibition. Whereas IPSPs in motoneurons are diminished or abolished by injections of strychnine, this drug has no effect upon presynaptic inhibition. Picrotoxin, on

the other hand, abolishes presynaptic inhibition without affecting postsynaptic inhibition. Strangely, barbiturates enhance presynaptic inhibition.

By using the criteria of latency and time course, depolarization of afferent terminals, and pharmacological analysis, it has been possible to demonstrate the existence of presynaptic inhibition at many places in the central nervous system. In the spinal cord, presynaptic inhibition is produced predominantly by cutaneous fibers, by fibers from spindles in flexor muscles, and by fibers from the corticospinal tract. These effects are exerted upon afferent input to motoneurons and to ascending sensory pathways. Similar effects are obtained at the main sensory nucleus of the trigeminal nerve. Figure 9 summarizes electron microscopic findings which are consonant with physiological experiments showing that the pyramidal tract can control synaptic transmission in the dorsal column nuclei by means of presynaptic inhibition. Note that some terminals form synaptic relation both with the dendrites and with the large presynaptic terminals which, as degeneration experiments show, originate from the

FIGURE 9. Diagram of certain connections in the cuneate nucleus based on electron microscopic findings correlated with degeneration experiments and electrophysiological findings. Myelinated somesthetic afferent fibers (cuneate tract) ascending in the dorsal columns of the spinal cord terminate on relay cell, which projects into ventrobasal thalamus via the medial lemniscus. The relay cells and terminals of the cuneate tract are both controlled by the pyramidal tract via interneurons. Pyramidal tract fibers diagrammed here originate in pericruciate cortex of cat or pre- and postcentral gyri in macaques. The axoaxonic synapses, a_1 and a_2 , presumably mediate the presynaptic inhibition observed to follow pyramidal tract or cortical stimulation, and b_1 and b_2 produce IPSPs or EPSPs in the relay cell. Possible connections for pre- and postsynaptic inhibition from collaterals from cuneate tract or axoaxonic contacts in the cuneate nucleus, probable basis for presynaptic depolarization. (*Exp. Neurol.*, 13: 218, 1965.)

cuneate tract. Similar anatomical arrangements have been observed in the lateral geniculate nucleus of cats and monkeys, and electrophysiological experiments demonstrate that the cerebral cortex and mesencephalic reticular formation control synaptic transmission through this nucleus partly by means of presynaptic inhibition.

Other Synapses and Phenomena

The anatomical arrangement of recurrent collaterals from the motor axons projecting onto Renshaw interneurons at the base of the ventral horn has been described above. Upon stimulation of the ventral roots these interneurons discharge at extremely high rates, up to 1,500 per second in the initial burst, for as long as 50 milliseconds. The time course of their discharge is correlated with IPSPs and inhibition of motoneurons. A similar arrangement, where axon collaterals play upon interneurons which in turn send inhibition back upon neighbors of the cell originally excited, has been found physiologically for the cells giving rise to the pyramidal tract (Betz cells), in the cuneate nucleus and ventrobasal complex of the thalamus, in the pyramidal cell system of the hippocampus, and in the olfactory bulb.

Functions. An obvious function for such an inhibitory system is the confinement of excitation to a discrete neural pathway. Once excitation is sufficient upon a given set of neurons, their discharge suppresses, by means of this "surround inhibition," any marginal tendency for neighboring cells to discharge, thus focusing and sharpening the center of activity. When such inhibitory feedback is widespread within an active system, it is also likely to engender rhythmic activity by locking inhibitory periods in phase for a large group of cells and thus synchronizing the probabilities of their discharge.

Specific neurons which serve as inhibitory interneurons have been identified in the hippocampus and cerebellum. In both these structures a very dense network of synapses envelops the soma of the hippocampal pyramidal cells or the cerebellar Purkinje cells. These axosomatic endings originate from "basket cells." The evidence that these basket cells give rise to inhibition is as follows. When intracellular records demonstrate prolonged and powerful IPSPs, extracellular records show that the focus of the inhibitory action is at the cell body and not in the dendrites. Such records are meaningful in the cerebellum and hippocampus because in these structures cell bodies are aligned in precise laminae. Since the axosomatic endings and only these endings are powerfully activated during IPSPs and since these endings arise predominantly from the basket cells, the latter must be inhibitory interneurons. On the rising phase of these IPSPs a ripple of high frequency activity can sometimes be observed which corresponds well with the frequency of cell discharge concurrently occurring

in regions where the basket cell bodies are known to be located.

For the hippocampus it can be shown that the basket cells are activated by antidromic stimulation of hippocampal pyramidal cell axons. The cerebellar basket cell system, on the other hand, is probably not activated by axons of the Purkinje cells since the latter are inhibitory in their effect.

It bears emphasis that axon collaterals from hippocampal pyramidal cells, Betz cells, or motoneurons are not likely to be the only input to the basket cells, Renshaw cells, or other interneurons responsible for recurrent inhibition. In other words, these inhibitory systems can probably be activated from several sources.

Synaptic transmitters

Acetylcholine. Since acetylcholine is released by motor axons at their presynaptic terminals on muscle fibers, it is reasonable to suppose that the axon collaterals of these same neurons would release acetylcholine upon Renshaw cells. The correctness of this expectation has been repeatedly confirmed in pharmacological experiments on spinal cord systems. One of the more striking is the demonstration that Renshaw cells are readily excited by the electrophoretic application of minute quantities of acetylcholine in their immediate vicinity by means of microelectrodes, whereas similar applications to other interneurons or to motoneurons is essentially without effect.

Similar electrophoretic application elsewhere in the brain demonstrates that about 10 to 25 per cent of the isolated neurons can be excited by acetylcholine, and roughly 5 per cent are inhibited by it. These effects have been particularly well studied in the neocortex. In the visual cortex of the cat cells responding at "on" "off" or at both "on" and "off" of light are affected or not affected by electrophoretic application of acetylcholine in the same proportion as other cortical neurons, i.e., about 20 per cent excited, 5 per cent inhibited. On the other hand, over 90 per cent of the Betz cells in the precruciate motor cortex of the cat are excited by acetylcholine whereas in the posteruciate area only 64 per cent of the pyramidal tract cells are cholinceptive, and only about 20 per cent of the nonpyramidal tract cells in these areas can be activated by acetylcholine. Throughout the cortex the cholinceptive cells do seem to lie in the deeper cortical layers, suggesting that they may be pyramidal cells in most instances.

The onset of the effect of acetylcholine is characteristically slower for cortical neurons than for Renshaw cells, and the effect outlasts the cessation of application by many seconds. Furthermore, the response of Renshaw cells to acetylcholine is "nicotinic" since it is blocked by curariform agents, whereas at the cortex, responses, particularly inhibitory responses, tend to be "muscarinic" in that they can be blocked by application of atropine or hyoscine but not by curariform agents. Cells in the mesencephalon and dienceph-

alone seem to give both muscarinic and nicotinic responses. While neurons of the lateral geniculate nucleus and the ventrobasal complex are cholinceptive, neither atropine nor curariform drugs block their response to stimulation of optic tract or medial lemniscus. This suggests that the cholinergic input to these nuclei arises from the centrencephalic system rather than from the specific optic or somesthetic afferents.

Stimulation of the mesencephalic reticular formation can activate cholinceptive units in neocortex, but the latency is rather long. While some such units have transcallosal afferents or afferents from nonspecific thalamic nuclei, most are activated best by stimulation of specific thalamic nuclei, although again the latencies are usually long. Thus it is still not possible to specify precisely the organization of corticopetal cholinergic systems. Electron microscopic evidence indicates that cholinesterase is located exclusively in the

type I axodendritic synapses, but, of course, no claim can be made that all such synapses are cholinergic. Differential staining techniques also indicate that neocortical pyramidal cells, the caudate nucleus, putamen, and septal nuclei have high concentrations of acetylcholinesterase.

Two other lines of evidence suggest that the foregoing experimental findings are actually related to functional cholinergic systems in the brain. First, acetylcholine is continuously released from the surface of the cerebral cortex and from the caudate nucleus. This release is increased several fold by direct electrical stimulation of these structures or, in the case of the somatosensory cortex, by stimulation of peripheral nerves but not by transcallosal stimulation. Second, acetylcholine is found in large amounts only in that fraction of brain homogenates which contains the synaptic vesicles.

It can thus be concluded with considerable confidence that acetylcholine functions as a transmitter at many synapses in the brain. However, there are still many difficulties involved in appraising these facts. For instance, acetylcholine excites some neurons and inhibits others. This perhaps should not be surprising since it produces hyperpolarizing potentials in the heart and in certain central synapses of snails and sea slugs but elicits depolarizing potentials at other central synapses in sea slugs, at vertebrate myoneural junctions, etc. The nature of the action of the transmitter may thus be determined by the subsynaptic membrane. There are several instances of neurons being excited or inhibited by more than one type of transmitter. For instance, while the nicotinic type of response is characteristic of Renshaw cells, there is some evidence that they possess still another type of acetylcholine receptor. Furthermore, when cholinergic transmission is blocked at Renshaw cells, they continue to respond vigorously to electrophoretic application of glutamic acid. Similarly, cells in the pons and medulla respond to electrophoretic application of acetylcholine, norepinephrine, and 5-hydroxytryptamine, giving various combinations of excitation and inhibition to these substances specific to any one cell. Finally, there is the complication (Figure 10) that two types of synaptic vesicles can be found in the same synaptic ending.

Amino acids. Much evidence is accumulating to indicate that γ -aminobutyric acid (GABA) is an inhibitory transmitter in the mammalian central nervous system. The evidence begins with the discovery that a factor, now identified as GABA, isolated from mammalian brain can cause inhibition of the stretch receptor neuron in the crayfish. The inhibitory axon which normally inhibits this cell in the crayfish contains very high concentrations of GABA, whereas adjacent axons which have an excitatory effect do not. The relevance of these facts to the mammalian central nervous system is that glutamic acid metabolism is uniquely important in brain as compared to

FIGURE 10. Two types of vesicles in single synaptic terminals in the anterior hypothalamus of the rat. SV, the common type of vesicle, with an average diameter of 400 to 500 Å, constituting about 80 per cent of the vesicles found in these hypothalamic terminals; dv, dense vesicle, identical in appearance with vesicles in proven adrenergic terminals. The dense vesicles have a mean diameter of about 1,300 Å and account for about 20 per cent of the vesicles present. Similar terminals with two types of vesicles have also been found in the thalamus. (From Pellegrino de Iraldi, A., Farini Duggan, H., and de Robertis, E. Adrenergic synaptic vesicles in the anterior hypothalamus of the rat. *Anat. Rec.*, 145: 521, 1963.)

other tissues (Section 2.5, Table I), and that brain but no other mammalian organ contains GABA in large amounts. GABA is found in highest concentration in the fractions of homogenized brain which contain the synaptic vesicles. It is released continuously from the surface of the neocortex in the resting state. During the slow wave phase of sleep this release increases 3-fold and is abolished during states of arousal maintained by occasional stimulation of the mesencephalic reticular system.

The Purkinje cells of the cerebellum produce IPSPs in the cells of Deiter's nucleus. Similar hyperpolarization is produced in Deiter's cells by electrophoretic application of GABA, and the Purkinje cells contain unusually high concentrations of GABA. Thus, several lines of evidence suggest a role for GABA as an inhibitory transmitter.

However, its electrophoretic application to most cells in the mammalian central nervous system, while inhibiting their discharge, does not produce in them the hyperpolarization that would be expected were GABA the transmitter producing IPSPs. Instead, the effect of GABA is more one of stabilizing the membrane potential so that both EPSPs and IPSPs are diminished. This is suggestively similar to the effect upon presynaptic terminals required to produce presynaptic inhibition. It is thus of interest that picrotoxin, which blocks presynaptic inhibition in the mammalian central nervous system, prevents the action of GABA in invertebrate systems. The case with Purkinje cells, however, is contrary to this supposition that GABA might be particularly related to presynaptic inhibition.

Many other neutral amino acids have effects similar to those of GABA, while acidic amino acids are uniformly excitatory. Certain amino acids can thus be grouped in pairs. Glutamic, aspartic, and cysteic acids have powerful excitatory effects upon all neurons to which they are electrophoretically applied, whereas their decarboxylated congeners, the neutral amino acids β -alanine, GABA, and taurine, respectively, depress the activity of all neurons. The uniformity of these effects upon all varieties of neurons and the failure of these compounds to imitate the actions of EPSPs and IPSPs make it difficult to conceive of these substances as being involved in the more usual forms of synaptic transmission.

Norepinephrine and serotonin. There is strong suggestive evidence that norepinephrine and possibly 5-hydroxytryptamine (serotonin) are active as synaptic transmitters in the central nervous system. These monoamines and their metabolites are of extraordinary interest because they are influenced by psychotropic drugs and appear to be abnormal in psychotic individuals (see Section 2.3). Norepinephrine (noradrenaline) is the transmitter at peripheral junctions of the sympathetic nervous system. Its immediate precursor is dopamine, which is ultimately derived from the amino acid phenylalanine. The amino

acid tryptophan, with its indole ring, yields 5-hydroxytryptamine through 5-hydroxytryptophan as an intermediate. Of the monoamines only the catecholamines norepinephrine and dopamine, and the indoleamine 5-hydroxytryptamine occur in brain in significant amounts.

When frozen tissues are dehydrated and then subjected to formaldehyde vapor at 80° C., a highly specific reaction occurs which converts monoamines into fluorescent compounds. With the use of this technique of fluorescence microscopy with careful controls, it is now possible to trace various monoamine systems in the brain with great accuracy. Such data confirm previous chemical analyses showing high concentrations of norepinephrine in the hypothalamus and of dopamine in the caudate nucleus and putamen. Monoamines are essentially absent in neocortex and cerebellum. Terminals containing norepinephrine or 5-hydroxytryptamine are found in the intermediolateral cell column of the spinal cord, and also upon motoneurons and in the substantia gelatinosa of Rolando in the dorsal horn. Cells containing monoamines occur in the raphe and ventrolateral nuclei of the reticular formation of the medulla, and intense stimulation for 1 to 2 hours at these loci halves the norepinephrine content of the spinal cord and diminishes the monoamine fluorescent reaction in the dorsal and ventral horns. Other monoamine-containing cells are found in the ventral tegmental area, substantia nigra, and mesencephalic reticular formation. By means of lesions it can be demonstrated that these neurons control the monoamine content of the forebrain, probably as contained in their axons and presynaptic terminals. Cutting the median forebrain bundle, subthalamic area, and cerebral peduncle produces a 75 per cent decrease in norepinephrine and 5-hydroxytryptamine levels and total loss of dopamine in the forebrain ipsilateral to the lesion. By fluorescence microscopy terminals containing dopamine are normally found in caudate and accumbens nuclei, the putamen, and the olfactory tubercle; norepinephrine in cingulate gyrus, pyriform cortex, amygdala, septum, hippocampus, preoptic area, and hypothalamus; and 5-hydroxytryptamine in the globus pallidus, septal area, amygdala, and hypothalamus. Almost all of these terminals are dependent upon the mesencephalic systems.

Electrophoretic application of these compounds through multibarrelled microelectrodes depresses the activity of cells in the neocortex and lateral geniculate nucleus. Since monoamines are not prominent at these loci (although they are found at a few bipolar-ganglion cell junctions in the retina), the significance of this is problematical. In the medulla, pons, and mesencephalon about half the neurons are inhibited, but 40 per cent are excited by 5-hydroxytryptamine, while with norepinephrine about 20 per cent are inhibited and 30 per cent excited. The time course of these effects, however, is rather slow.

Since cell bodies, axons, and terminals all show

fluorescence, the monoamines are probably manufactured in the cell body and passed down the axon. When the sciatic nerve is compressed, an accumulation of fluorescing material, probably norepinephrine, begins within 12 hours in the central portion of the compressed axons. It is not known whether, in addition to receiving norepinephrine via the axoplasm, the presynaptic terminals are themselves capable of synthesizing it. They do, however, absorb norepinephrine when it is present in their environment. This characteristic is of value in further identifying adrenergic terminals by their absorption of tritiated norepinephrine. In adrenergic terminals of the peripheral nervous system, and in association with tritiated norepinephrine, large synaptic vesicles are consistently found with dense osmiophilic cores (Figure 10). As with acetylcholine and GABA, the monoamines and their relevant enzymes are found predominantly in those fractions of homogenized brain which contain synaptic vesicles.

Conclusions. In summary, acetylcholine, GABA, norepinephrine, and 5-hydroxytryptamine are all likely to be central synaptic transmitters. The analysis is complicated by the probability that the type of response which each produces may be determined predominantly by the nature of the postsynaptic membrane. There may also be many transmitter substances still undiscovered since those at hand are not very successful in imitating the phenomena of central synaptic excitation and inhibition.

Postsynaptic inhibition in the spinal cord may differ from that in the brain stem and cortex since in the cord IPSPs endure only about 12 milliseconds and are blocked by strychnine whereas above the obex 200-millisecond IPSPs are the rule and strychnine has no effect on them. The morphology of synapses and synaptic vesicles has to date posed far more difficult problems than it has solved. First among these is the occurrence of two types of vesicles in one synapse (Figure 10). While this might be merely an outcome of the specificity of subsynaptic membranes (i.e., the presynaptic terminal serves a cafeteria selection of transmitters and the subsynaptic membrane takes its choice), the significance is likely to be more subtle and reflect a greater efficiency than this. It seems likely, however, that the smaller vesicles with osmophobic cores may contain any of several transmitters. Thus there is no apparent difference in vesicles at axosomatic endings which electrophysiological evidence indicates are inhibitory from those in the presumably excitatory endings on the dendrites. Nor does the difference in type I versus type II endings specify excitation versus inhibition since inhibitory action also seems to impinge upon dendrites whereas type II synapses do not. Finally, there are instances where vesicles occur on each side of what seem to be junctions between dendrites!

Enduring Consequences of Synaptic Action

Rapid, repetitive activation of synapses produces changes in their effectiveness both during the course of activation and for a considerable period thereafter. For continuous stimulation of afferents from muscle spindles, EPSPs evoked in motoneurons remain relatively constant until stimuli occur at 0.5 per second. The amplitude of the EPSPs then falls with increasing frequency until at 10 per second it is only about 85 per cent of control levels. With further increase of frequency, however, the amplitude recovers until at about 50 per second

it is restored to control levels and then falls off again to reach 90 per cent at 100 per second. The size of the EPSP probably reflects the amount of transmitter released. These synapses thus operate with greater efficiency at 50 per second than at 20 per second, but optimally and minimally effective frequencies vary with different synaptic systems. The total amount of transmitter released per unit of time will, of course, be much greater at 100 than at 50 per second even though the amplitude of each EPSP is smaller, and indeed the maximum rate of release is reached only at 300 per second.

Some synaptic systems become and remain inoperative during rapid stimulation, a phenomenon known as "Vedensky inhibition." Such suspension of function could arise in several different ways: (1) by refractoriness in presynaptic terminals rendering them inexcitable, (2) by depletion of immediately available transmitter, (3) by a saturation of the postsynaptic membrane with the transmitter, thus desensitizing the EPSP or IPSP mechanism, or (4) by keeping the postsynaptic cell continuously depolarized beyond its threshold level and thus inactivating it.

With onset of a burst of stimuli there is a brief period of depression and adjustment before the EPSPs attain a stable level. Presumably a mobilization of transmitter from presynaptic sources is required to accommodate the greatly augmented rate of its release. Once such mobilization is achieved, it remains accessible for several minutes following a few seconds of high frequency stimulation. In systems where MEPPs are observed, their rate increases greatly during this postactivation period. The amplitude of EPSPs to single stimuli actually increases only 1.5 to 2 times following intense activity (e.g., tetanization at 200 per second for 15 seconds), but this moderate increase often is enough to discharge 4 to 10 times as many cells in a motoneuronal pool as did the same stimulus prior to tetanization. Naturally, if the stimulus initially discharges all the cells, it can do no more and therefore no potentiation of reflex discharge can be obtained even by doubling the amplitude of EPSPs. The magnitude of possible potentiation is thus a function of the number of cells subliminally excited by the original stimulus; i.e., it is dependent upon the existence of a "subliminal fringe."

In work with monosynaptic reflexes in the spinal cord it can be shown that the locus of the augmented responsiveness is in the presynaptic terminals which are subjected to the tetanization. During the period of potentiation the excitability of the tetanized afferent fibers is unchanged, as is the antidromic response of the motoneurons or their responsiveness concurrently tested via nontetanized synaptic systems. The effect is thus limited to the activated synapses. The presynaptic terminals of the potentiated system are hyperpolarized, a common finding in fibers of small diameter following intense activity. As discussed above for the myoneural junction, such hyperpolarization could account for an increase in the release of transmitter for each impulse that succeeds in invading the terminal. Attractive as such an explanation of postactivation potentiation may be, it probably is not altogether true since a 3- to 8-fold postactivation increase in EPSPs is obtained in the ciliary ganglion of the chick while both direct and indirect measurements show no change in amplitude of presynaptic spikes.

The existence of synaptic changes that endure for minutes rather than milliseconds is of obvious interest in behavioral contexts. The interest is further enhanced by certain cases where these effects last for hours. If a dorsal root is severed distal to the ganglion, the central projections survive but are wholly inactive because of lack of peripheral stimulation. After a few weeks the reflexes evoked by electrical stimulation of such "unused" dorsal roots are greatly diminished in comparison to similarly evoked reflexes on the intact side. Tetanization of the "unused" paths, however, restores their efficacy to near normal levels, and the restoration survives for several hours. Potentiation and depression of synaptic transmission in the lateral geniculate nucleus of cats under barbiturate anesthesia also can endure for hours, depending upon conditions of stimulation.

If synaptic systems A and B are both able to discharge the same interneuron and if the interneuron follows high frequency stimuli, then potentiation established by activity in system A (and the interneuron) will also be accessible via system B. Examples of such "transferable" potentiation have been studied in the mammalian spinal cord. At first glance this seems relevant to phenomena of learning. More careful consideration, however, reveals in this paradigm the present shortcomings of "synaptology" in explaining learning or, perhaps more important, reveals a peculiarity of the temporal organization of learning. Following activity in A the effectiveness of B (and of A) will be changed for a relatively long time. In other words, antecedent action in one system produces a protracted change in the consequences of subsequent action in another system. This makes neurophysiological sense but is exactly the opposite of what happens in learning. In learning, the consequences change not for the subsequent stimulus but for the antecedent! This temporal paradox is easiest to illustrate with conditioned reflexes, although it applies to many other situations. In behavioral conditioning the antecedent stimulus, A, is the conditional stimulus and the subsequent stimulus, B, is the unconditional stimulus. During the course of conditioning a change occurs so that the consequences of "A" are altered, whereas the response to the subsequent stimulus, "B," remains relatively constant. Until very recently there was no known neurophysiological parallel to such retrospective alterations.

They have now, however, been observed in certain small cells in the abdominal ganglion of the sea slug, *Aplysia depilans*. In about 15 per cent of these cells the following phenomenon could be observed. Repeated stimulation of a powerful afferent system which evokes large EPSPs and discharges the cell has no effect upon the EPSPs subsequently evoked by stimulation of a different, less effective afferent system. Thus the postactivation paradigm above is not fulfilled. If, however, the stimuli are paired, so that the less effective stimulus is repeatedly given 0.3 to 0.5 second prior to the highly effective stimulus, the EPSP evoked by the first stimulus gradually increases, often to the point where it too can discharge the cell!

While the increase in effectiveness of the antecedent stimulus gradually subsides after pairing ceases, some augmentation endures for 4 to 20 minutes.

The experiment with *A. depilans* thus duplicates exactly the temporal paradox of learning. Further, it provides the basis for a general hypothesis concerning synaptic alterations underlying conditioned reflexes. It is proposed that for a brief period following its excitation and only at such times a synaptic terminal is permeable to material from neighboring terminals, from other axons ending upon it, or from the subsynaptic membrane. If, during this period of heightened permeability, discharge also occurs in a more effective synaptic system, material (i.e., synaptic vesicles) from the second system will be incorporated into the first and alter its characteristics. There are many ramifications to such a proposal, but only two need be mentioned here. First, such alteration of synaptic effectiveness will depend not only upon timing and relative potency of the synaptic actions but upon the contiguity of the synapses. In *A. depilans* relatively few cells seem to have the appropriate arrangements for this effect. It is thus possible that certain cell types are specialized to support this phenomenon. Second, if such enhancement is effected via chemical exchange, the role of the synaptic vesicle is extended in scope. It becomes then not merely a packet of transmitter, but "a set of instructions" for contiguous cells, available only in the circumstance of precisely time-locked action.

While such speculations obviously are far afield from the sea slug, they perhaps illustrate why an understanding of synapses may yet be important for students of behavior—if only to deal with such speculations.

Suggested Cross References

Further information regarding the nature and functions of neural transmitters and their relationship to psychoactive drugs may be found in Section 2.3. The EEG is discussed in numerous contexts throughout the book, especially in Chapter 10, on neurology; in Chapters 18, 19, 20, and 21, on organic brain disorders in adults; and in Section 42.3, on brain disorders in children.

2.7 ELECTRICAL ACTIVITY OF THE BRAIN

ROBERT W. DOTY, Ph.D.

CHARLES J. SMITH, Ph.D.

Dendrites

Problem. The cerebral cortex and other masses of uniformly oriented neurons cannot be understood until it is known how dendrites function in neural processes. One of the first questions to be asked is whether the alignment and packing of dendrites (Figure 1) serves to promote some interchange of information among them, or whether this arrangement is but a convenience of developmental organization, lacking major functional import. The dendrites comprise 30 per cent or more of the cortical volume but make up 90 per cent of the surface area of cortical neurons. About 2,000 to 4,000 other neural cell bodies, to say nothing of other dendrites, lie within the dendritic field of each stellate cell or among the basal dendrites of each pyramidal cell. The opportunities for intercommunication are thus enormous for each cell, and it is difficult to conceive how any precision of integration could be obtained were each cortical neuron diffusely influenced by the activity of its neighbors. Indeed, such little knowledge as is available points to the likelihood that cortical neurons perform their integrative functions despite rather than by means of electrochemical gradients produced by their orientation en masse (see below and Figure 2, Part II). The chemical step in synaptic transmission, the intricate morphology of synapses and the synaptic spine apparatus (Figures 1, 2, and 3 in Section 2.5, and Figure 4 in Section 2.6) all seem admirably adapted for assuring highly specific influences between cells, and for excluding interference from possibly irrelevant action merely by reason of cellular adjacency.

Modality-specific cell columns. Under light barbiturate anesthesia the cells in somesthetic and visual cortical areas of cats and somesthetic areas in macaques (Figure 3) are found to be organized into modality-specific columns. This is evidenced by the fact (e.g., Figure 3) that a microelectrode passing through the cortex perpendicular to its surface encounters cells of similar function throughout the entire course of the track. Similar observations have been made for auditory cortical projection areas and the

"motor" cortex of the cat. The "modalities" in these columns are not the usual ones of touch, temperature, or color, but rather are related to location of the receptors and/or a particular pattern of stimulation such as, in the case of the visual system, direction of movement. The diameter of such a column is difficult to estimate but probably does not average much more than 500 μ .

The strong organization of vertically directed systems is readily apparent in the histological structure throughout the cortex (Figure 1). The columnar arrangement thus probably forms a basic unit of cortical function. Dividing the cortex vertically into a grid of small islands effects no great change in its ability to integrate complex behavior. Nor does circumsecting a cortical region in which electrical stimulation serves as a signal for performing a learned act alter the performance, whereas limiting the spread of excitation to transcortical pathways at first abolishes the response. These meagre behavioral data are at least concordant with the concept that cortical function has a strong vertical organization which is effective despite limitation of tangential, intracortical elaboration. It is thus possible at this stage to picture the cortex as a mosaic of functionally specific columns. The great interdigitation of dendrites between neighboring columns (Figure 1A) would defeat the specificity of such an arrangement were there to be significant "cross talk" between these intertwined elements.

Recent electron microscopic observations in the olfactory bulb and retina have suggested the existence of reciprocal "dendrodendritic" synapses, i.e., contacts between apparent dendrites in which synaptic vesicles are seen on both sides. Specific dendrodendritic interactions might thus occur. However, the contacts so far have not been seen in other areas, and the two locations where they have been found are noted for "amacrine" cells which, in the classical description, lack axons. The reciprocal dendrodendritic synapse may reflect merely a peculiarity of this type of neuron.

Properties of dendrites. The problem remains as to the role of dendrites. The high internal resistance of terminal dendrites, arising from their small diameter, presents a serious impediment for the spread of electrotonic potentials or the propagation of action potentials. Yet without propagation it is apparent that the great numbers of synapses on distal dendrites (Figures 2 and 3 in Section 2.5 and Figure 1 herein) must lack significant influence on the electrical behavior of the neuron and its generation of spike discharges. While much still remains to be learned about the operation of this seemingly paradoxical arrangement, data from the hippocampus and dorsal horn of the spinal cord suggest an explanation along the following lines. Postsynaptic potentials in the dendrites, when sufficiently numerous or when occurring in proximal portions, exert an electrotonic influence on the soma and the trigger zone in the initial segment of the axon, thus influencing the threshold for "all or none" discharge. Since the spike potential usually does not propagate very far into the dendrites, this electrotonic influence survives essentially unaltered by soma-axon behavior. Under certain conditions of spatial or temporal synchronization of afferent bombardment the dendrites may become sufficiently depolarized to conduct an action potential, at about 200 to 400 μ per millisecond, towards the soma and thus provide an additional trigger zone in the

FIGURE 1. *A*, drawing of Golgi-stained neurons in parietal lobe of a 1-month-old human infant; *B*, composite picture made of camera lucida drawings from Golgi and Golgi-Cox preparations of brains of mouse and rat, showing general arrangement of various neurons in cerebral cortex. 1, recurrent afferent fiber from thalamus, which ascends to molecular layer, runs for a short distance horizontally and then descends and terminates in fourth layer with repeated branchings; 2, special afferent from thalamus terminating in fourth layer with profuse arborizations; 3, short axon cell in second layer; 4, 5, and 6, three Cajal cells with their horizontal fibers in molecular layer; 9 and 10, medium pyramidal cells in third layer; 11, 12 and 13, large pyramidal cells in fifth layer; 14, typical Golgi type II or stellate cell in fourth layer; 15, medium sized pyramidal cell in sixth layer, with apical dendrites which usually do not reach molecular layer; 16, Martinotti cell; 17, shaft and apical dendrites of pyramidal cells the cell body and axon of which were left undrawn. Consejo Superior de Investigaciones Científicas, Madrid, 1955. *Part B* is from Chang, H-T. Dendritic potential of cortical neurons produced by direct electrical stimulation of the cerebral cortex. *J. Neurophysiol.*, 14: 1, 1951.)

proximal dendrites for eliciting spike potentials in the soma and axon. A proximo-distal gradient in synaptic effectiveness seems an inevitable consequence of dendritic structure and performance. Influenced by subtle intracellular chemical changes associated with correlated discharge, as discussed at the end of the preceding chapter, synaptic endings might gradually migrate from distal dendrites to a proximal and more effective position for controlling the behavior of the cell upon which they terminate and thus provide a basis for some of the phenomena of learning. While such migration, of course, is pure speculation, it is of considerable interest that the various synaptic systems terminating upon the dendrites of hippocampal pyramidal cells do so in an orderly fashion so that each system has a strong predilection for ending at a particular proximo-distal level along the dendritic system.

Evoked Potentials

Location of activity. Within the 2-mm. thickness of the neocortex about 50,000 neurons would lie directly under an electrode having a 1-mm.² contact with the surface. Roughly 75,000 fibers would be leaving and 25,000 entering the cortex in the subtended area. The great majority of fibers are about 1 μ in diameter and roughly 80 per cent are less than 2 μ . The discrepancy between number of cortical cells and efferent fibers indicates both the possibility of branching and the inadequacy of available data.

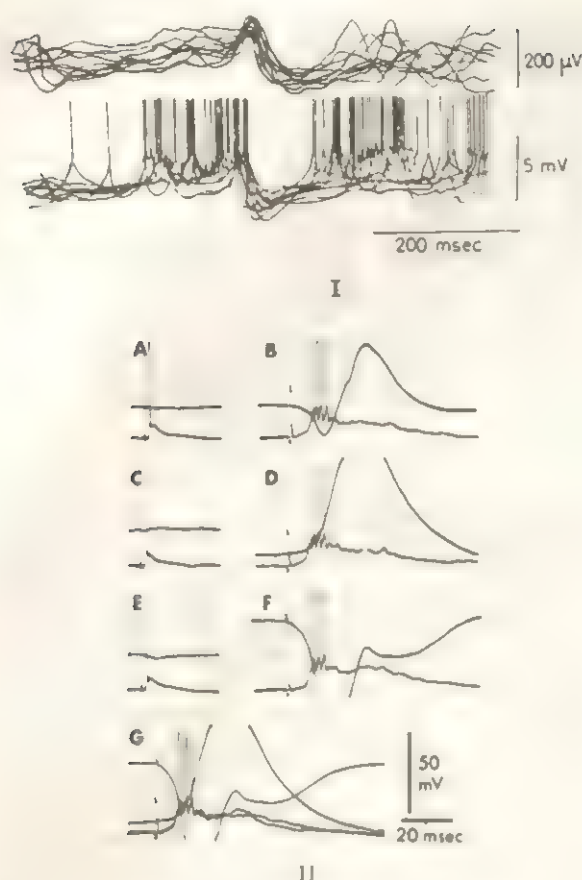

FIGURE 2. Correlation (I) and lack of correlation (II) between electrical activity recorded from the surface of the cerebral cortex and activity of immediately subjacent neurons. Upper channel is EEG of pericruciate cortex in the cat, negative deflection upwards; lower channel, intracellular record from Betz cell. I, Superposition of nine traces phased at peak of a spontaneously recurring negative wave reveals that the cell invariably discharges during an EPSP occurring during the rising negativity and then undergoes a hyperpolarization for about 100 milliseconds during the surface-positive phase of the wave. II, A, C, and E, intracellular response to antidromic stimulation of medullary pyramid showing shock artifact and spike, and delayed depolarization which remains unchanged during surface polarization. B, fully developed augmenting response from stimulation of ventrolateral nucleus. A prolonged EPSP begins about 6 milliseconds after the stimulus, and three spikes are discharged during the surface positivity. In C and D, anodal, in E and F, cathodal polarizing currents, 50 μ amp. per mm.² are applied to the cortex just above the impaled Betz cell. The polarity of the augmenting response is dramatically reversed by the polarization, but the Betz cell's response is unaltered, as shown in G by superposition of traces taken under the two conditions. (Part I is from Creutzfeldt, O. D., Watanabe, S., and Lux, H. D. Relations between EEG phenomena and potentials of single cortical cells. II. Spontaneous and convulsoid activity. *EEG Clin. Neurophysiol.*, 20: 19, 1966. Part II is from Purpura, D. P., and McMurty, J. G. Intracellular activities and evoked potential changes during polarization of motor cortex. *J. Neurophysiol.*, 28: 166, 1965.)

The surface electrode will record the action of subjacent and neighboring elements in proportion to their degree of synchronous phasing and inverse proportion to their distance from the electrode. A 100- μ V. potential might thus represent very strong, synchronous action at a considerable distance

from the electrode, or a rather weak action in its immediate vicinity. The true nature of a response thus cannot be determined with a single, stationary electrode. The same is true for the polarity of the response. A depolarizing action (i.e., excitatory postsynaptic potentials (EPSPs)) will appear negative to an electrode at the site of action. However, since the depolarization is occurring in a conducting medium, currents will flow from the surround, which acts as a "source" for the current flowing to the negative or "sink" area. Thus an electrode remote from the site of depolarizing action will record positivity. The reverse holds true for hyperpolarizing (inhibitory postsynaptic potential (IPSP)) activity. It follows that an electrode may become positive because of remote EPSPs or spike activity, or because of IPSPs in its immediate vicinity. Analysis of cortical potentials thus requires tracking the electrode through the cortical mass to determine the origin (by amplitude) and true polarity of the responses obtained. Since the cells of any one type are not very precisely aligned in depth and several types, which may have widely differing characteristics, may be concurrently active in any particular layer, interpretation of intracortical electrical events is difficult; but there are certain consistent features about which some certainty exists.

Response to thalamic afferents. When an electrical stimulus is applied to a thalamic relay nucleus, such as the lateral or medial geniculate nuclei or the ventrobasal complex, a highly synchronous volley ascends the afferent fibers to the corresponding cortical projection areas. There the afferent terminals effect predominantly excitatory connections with the stellate cells centered around layer IV. These in turn immediately relay the excitation into a second set of cells, and probably then to a third set, each relay ascending closer towards the surface. All these events are registered as positive deflections at the surface lasting roughly 1 millisecond each, corresponding to spike potentials. A much slower negative-positive sequence, undoubtedly the result of postsynaptic potentials then ensues.

This sequence is characteristic of "sensory" cortex activated by highly synchronous volleys from specific afferents. Much different sequences are seen in other cortical areas or with other types of stimuli. With natural stimuli having abrupt onset, e.g., flashes, clicks, or tapping the skin, positive-negative sequences reminiscent of these electrically evoked responses can be obtained in the appropriate sensory areas (e.g., Figure 4, Part I). Abruptness of onset is necessary to synchronize the action that it may be detected as different from the background, spontaneous activity. Since the response is relatively constant in amplitude and latency, and the background action usually random with respect to it, repetition of the stimulus and summing of the activity in the immediate poststimulus period will enhance the response and cancel the background. By this technique of "averaging" it is even possible to record such evoked potentials through the human scalp 2 cm. or so from the brain. The intervening tissue seriously distorts and diminishes the potentials, and scalp electrodes inevitably record from a very large area in comparison with those in direct contact with the brain. The response recorded will obviously depend upon the complex spatial relations between the electrodes and the responding area, and it may also very well be that individual brains even in animals have highly individual types of response could the technical problems only be resolved to reveal it. In any event, under standardized conditions the evoked response in man is exceedingly stable and can be as characteristic of the individual as his fingerprints (Figure 5).

FIGURE 3. Modality-specific columns of cells in somatosensory cortex of postcentral gyrus of lightly anesthetized macaque. *Inset in Part I* indicates (A) level of penetration of microelectrode in relation to cytoarchitectonic pattern (Brodmann areas 1, 2, and 3; CS, central sulcus, PCS, postcentral sulcus). Three penetrations are reconstructed at upper right showing passage of electrode first through area 1, then into area 3. Grayed portion of track, multiunit recording; dark bars, single units. Excitation by light touch of the skin represented to left of line of penetration, to right for excitation by rotation of joints or pressure on fascia or periosteum. When penetration is perpendicular to surface, only one of these forms of excitation is effective along the entire track, but when the penetration passes tangentially through the cortex (as in area 3), the effective modality often changes with progression of the electrode. Part II shows receptive fields determined for 7 of the 23 units encountered at the indicated depths along the right-hand track in Part I. Note that fields have similar location along any particular portion of the penetration. (From Powell, T. P. S., and Mountcastle, V. B. Some aspects of the functional organization of the cortex of the postcentral gyrus of the monkey: a correlation of findings obtained in a single unit analysis with cytoarchitecture. *Bull. Johns Hopkins Hosp.*, 105: 133, 1959.)

FIGURE 4. Photically evoked potentials and their alterations under various conditions in the primate visual system. I. and II, response in squirrel monkeys to brilliant, 10-microsecond strobotron flash. I, A and B, alert monkey with chronically implanted electrodes, oscillations at 160 per second in tract, 200 per second appearing about 15 milliseconds later in area striata. I, C, same animal under Nembutal anesthesia which almost abolishes cortical response while leaving substantial activity in the optic tract. Time calibrations: A, 10 milliseconds; B, 40 milliseconds; C, 20 milliseconds. II, another monkey under Dial anesthesia. II, A, background activity in optic radiation; B, response to flash delivered at moment of artifact; C, slight evoked potential and greatly augmented background activity following single pulse applied to mesen-

Direct cortical response. Electrical stimulation of the cortex evokes a direct cortical response (DCR) which reveals a number of important properties of cortical organization. A weak stimulus applied to the surface evokes a simple, almost monophasic surface-negative wave, lasting 10 to 20 milliseconds and propagating for about 5 mm. from the point of stimulation at a velocity of 0.7 to 2 m. per second. Stimulating with a penetrating electrode, this simple surface-negative response is no longer obtained after penetrating more than 0.1 mm. into the cortex. Its lateral propagation is abolished by cuts limited to the molecular layer (*layer I*, Figure 1B), while propagation is undisturbed if all the remaining cortex is cut through save the molecular layer. It thus appears that this must be the response of the apical dendrites and horizontal cells of Cajal. The latter are reputed to be rare in adult cortex, but the conduction velocity of the surface-negative DCR is faster than that found in the dendrites of hippocampal pyramidal cells, the distances of propagation are greater than the lateral extent of all but a very few apical dendrites, and the duration of the response indicates that it is postsynaptic. It is perhaps significant that there is no sign of IPSPs in this response of the molecular layer, again suggesting the association of hyperpolarizing responses with the soma rather than dendrites.

cephalic reticular formation at beginning of trace; D, response to flash delivered 33 milliseconds after pulse applied to reticular system, i.e., about 50 milliseconds prior to appearance of photically elicited response in the central nervous system. Note great augmentation of response when preceded by mesencephalic stimulation. (Part I is from Doty, R. W., and Kimura, D. S. Oscillatory potentials in the visual system of cats and monkeys. *J. Physiol.*, 168: 205, 1963. Part II, Doty, unpublished.)

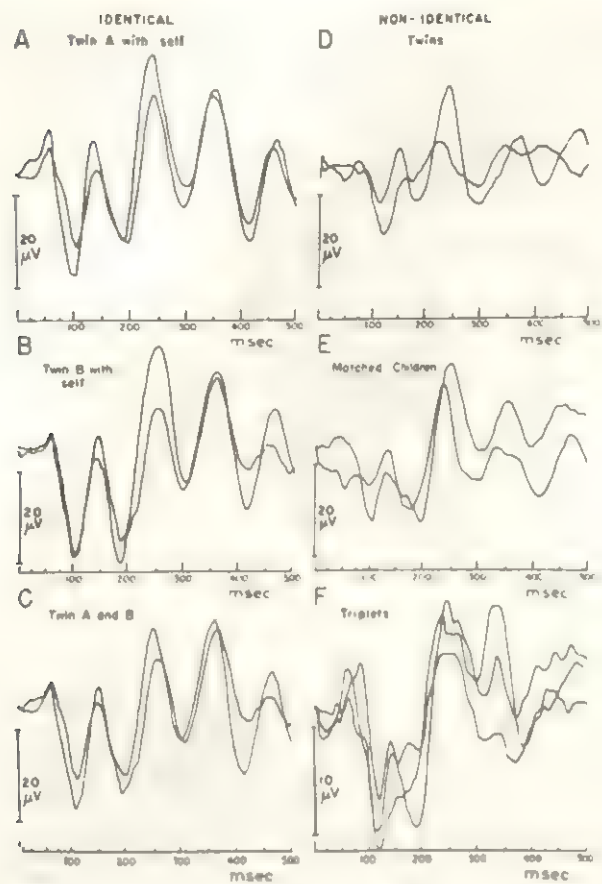

FIGURE 5. High degree of reproducibility and genetic determination of wave forms of potentials evoked in human occipital lobes by flashes of light under carefully standardized conditions. Averages of responses to 100 flashes delivered 1 per 3 seconds. *A* and *B*, records from identical twins taken 6 months apart and superimposed for comparison; *C*, one record from each twin; *D*, records from nonidentical twins; *E*, two unrelated children of same age as the twins and triplets; *F*, triplets. Correlation coefficients for curves from identical twins (*A*, *B*, *C*) were 0.90, for *D*, 0.53; for *E*, 0.64. (From Dustman, R. E., and Beck, E. C. The visually evoked potential in twins. *EEG Clin. Neurophysiol.*, 19: 570, 1965.)

With stronger stimulation a further negative component is added which appears 5 mm. from the point of stimulation, diminishes with further distance, but then is "reinforced," i.e., becomes larger again at a 10-mm. distance. This additional negative response is undoubtedly synaptically propagated, apparently through "U" fibers just beneath the cortex, but its conduction time is only slightly longer than that for the primary negative wave and hence must be propagated in faster fibers.

Intracortical stimulation at various depths evokes more complex types of response. In "sensory" but not other types of cortex stimulation at or below layer IV evokes the same type of response as does stimulation of the thalamic relay nucleus.

Surface stimulation at an intensity double that for the threshold of the primary negative wave and eliciting about 20 per cent of the maximal response of the latter also produces a surface-positive wave if applied to unanesthetized cortex. The strength required is approximately the same as that for eliciting discharge in Betz cells. This positivity can propagate without attenuation through many millimeters of cortex at a velocity of 0.1 to 0.2 m. per second. The positive response has a duration of more than a second and is characterized by an overlying ripple of very fast activity, indicating that it arises

from a burst discharge of neurons deep within the cortex (where concurrently intense negativity and spike discharges can be recorded). Most interestingly, this burst discharge continues to recur aperiodically for up to an hour after 5 to 10 stimuli and requires no extracortical interchange since it proceeds best in neuronally isolated slabs of cortex.

Antidromic effects. With antidromic stimulation of the pyramidal tract it can be shown that Betz cells give off recurrent collaterals intracortically, producing an inhibitory effect for 100 to 200 milliseconds. Such analysis is not possible for other cortical areas since purely antidromic responses cannot be obtained. However, it is likely that recurrent inhibition plays an important role in cortical function just as it does in the spinal cord and elsewhere.

Cells sending axons to pyramidal tract. The opportunity to analyze the behavior of a specifiable type of cortical neuron, as offered by the pyramidal tract systems (Figure 2, Part II), provides much fascinating information. The pyramidal tract (PT) cells can be influenced and discharged by a great variety of inputs. Some of them respond to flashes and clicks as well as to somatosensory stimuli to either side of the body. The PT cells have a wider and much more flexible responsiveness than do other, non-PT neurons encountered in the same microelectrode penetration. The recurrent inhibition, set up by antidromic stimulation of the pyramidal tract, is particularly effective in curtailing their response to marginally excitatory stimuli. The contrast with responses of non-PT cells in the somatosensory cortical projection area immediately posterior to the "motor" area is striking. Cells of the latter type respond only to a single modality of stimulation applied to a restricted, relatively fixed area of the body, topographically related to areas giving responses in neighboring cells (Figure 3). Non-PT cells in the somesthetic area do not respond to proprioceptive stimuli, e.g., from muscle spindles, whereas such stimulation is effective on PT cells. In summary, the cells of the cortical somatosensory system respond predictably as expected from anatomically fixed paths, whereas the response of PT cells is labile and available over functionally fluctuating pathways.

The latter arrangement has obvious importance. When a monkey is trained to make a highly specific movement upon command, e.g., to a flash, it is found in the precentral gyrus that the PT cells controlling the learned movement begin to fire within 70 milliseconds after the onset of the response which the flash evokes in area striata. The pathways involved in exciting PT cells optionally by flashes are still unknown, but the techniques do seem to be available for determining the location and nature of the events occurring in this critical 70 millisecond period of "voluntary decision." Much of it may be via cortico-cortical connections since recent findings in cats show that responses to flashes can be obtained in several cortical areas, including precruciate "motor" areas and the orbital gyrus, even though the entire diencephalon has been removed with the exception of the lateral geniculate nucleus.

Direct Current Potentials and Polarization

Characteristics. A nonpolarizable electrode placed on neocortex records a positive D.C. potential, usually of several millivolts, in reference to other points such as the lateral ventricle, sciatic nerve, or frontal sinus.

Typical values are: 0.5 to 5 mv. for unanesthetized rabbits; 1 mv. for neonate rats, increasing with age to as much as 20 mv. in adults; 0.3 to 7 mv. in man. So long as conditions remain

constant and there is no stimulation or change in alertness of the individual, the potential remains steady.

The sources of this potential are undoubtedly various. Of greatest interest is the probable contribution of gradients in potential between neuron soma and dendrites. While the staggering of cell bodies in neocortex makes it impossible to obtain meaningful measurement there, analysis of the uniformly oriented hippocampal pyramidal cells shows the soma to be negative with respect both to apical dendrites and to basilar dendrites plus axon. Some of the surface positivity of neocortex thus undoubtedly arises because of the polarization of apical dendrites with respect to soma. Measurements of intracortical potential gradients are at least consistent with this idea, as are the rapid changes produced by sensory or centrencephalic stimulation. A slight decrease in the D.C. potential of the cortical visual area may be the first detectable response to stimulation of the optic tract too weak to elicit the usual evoked potential sequence. With more intense sensory stimulation a negative shift of a few hundred microvolts lasting several hundred milliseconds and followed by an equivalent enhancement of positivity is the unending accompaniment of evoked potentials, although not commonly recorded because of technical difficulties. These short latency, brief shifts in D.C. potential can be assigned with certainty to neural action in the vicinity of the cortical electrode. The source of more protracted changes is not so clear. For instance, in passing from stages of sleep with high voltage, slow electroencephalogram (EEG) to either wakefulness or paradoxical sleep, a 50 to 500 μ v. negative shift occurs in the D.C. potential and is accompanied by an increase in brain temperature of up to 0.6° C. The opposite changes occur when the EEG passes from low voltage, fast activity to high voltage, slow activity. However, since the D.C. potential of the entire brain, i.e., white matter as well as cortex, changes to about the same degree, it probably originates in metabolic effects or alterations of the blood-brain barrier.

Voluntary movement in man is preceded for about 1 second by a gradually increasing negative shift of the cortical D.C. potential. This "contingent negative variation," or "Bereitschaft," (readiness) potential occurs over wide areas of the scalp, although it is most fully developed over the precentral area contralateral to the moved limb. It appears in preparation for a movement even though the movement may then be withheld, and in this respect it is the response to a contingency. Within 30 to 90 milliseconds after the beginning of muscle contraction a complex, surface-positive evoked potential begins, representing the afferent discharge initiated by the movement itself. The latter, but not the former, occurs almost equally well if the limb is moved passively in the same manner by external manipulation. An apparently similar negative shift accompanies movement in rats and is of the same genre as the negative shifts occurring with arousal reactions in the EEG. A 6 to 9 per second rhythm in midline thalamic structures and dorsal hippocampus also precedes the initiation of movement by rats. The possible relation of these subcortical events to human volition remains unstudied.

Infra-slow oscillations. Semirhythmic, "infra-slow" oscillations in the D.C. potential, 0.3 to 1.5 mv., 0.5 to 8 per minute have been recorded from neocortex and hypothalamus in rabbits. Such oscillations are absent from thalamus, periaqueductal gray, and the mesencephalic reticular formation and indeed seem to be relatively independent of influence from these sys-

tems since mesencephalic stimulation, for instance, which produces an arousal reaction in the EEG does not alter the infra-slow oscillations. On the other hand, repeated stimulation of the ventromedial nucleus of the hypothalamus or other stressful procedures favor their development. The rhythm is not necessarily the same in various areas of the cortex, but cortical excitability is to some degree modulated by these oscillations. Their source seems to be in metabolic and hormonal factors, but their significance remains to be evaluated.

Spreading depression. Another form of D.C. shift is definitely pathological. This is the phenomenon of "spreading depression" which is a complex of electrical, metabolic, and circulatory changes elicited most readily by strong electrical or mechanical stimulation, or certain agents such as KCl, applied to neocortex. It can also be elicited in other regions of the brain but is most readily obtainable from cortex that has been maltreated by cooling or drying. It is probably the immediate cause in man of the phenomenon of scintillating scotoma. Upon application of the abnormally strong stimulus a wave of depression of all background and evoked electrical activity begins and spreads from the initiating area in all directions with a velocity of about 5×10^{-3} m. per second, i.e., 2 to 3 mm. per minute. With this very slow progression of the wave, the depression endures from 2 to 6 minutes at a given point, and recovery requires 10 to 15 minutes. The advancing wave is heralded by an intense surface negativity of 3 to 15 mv. which persists throughout the depression and is accompanied by a fall of pO_2 , cortical volume, and a visible vasoconstriction. The wave can propagate via any cortical layer save the first and is resistant to deep anesthesia. The apparent cause of this remarkable phenomenon is a convulsive outburst of activity which is so intense that the stimulated neurons lose sufficient K^+ to change the ionic environment of their neighbors, thereby depolarizing them and causing their intense discharge, etc. The evidence in support of this explanation, besides its inherent plausibility, is the recording of a prolonged burst of single cell activity at the advancing edge of the wave, the leakage of K^+ accompanying the phenomenon, its ready production by KCl, and the migration of Cl^- into the apical dendrites (probably in association with Na^+) during spreading depression.

Failure to recognize this phenomenon in certain earlier electrophysiological experiments led to some serious misconceptions. Among these was the scheme of "suppressor strips," still having its 20-year run in certain texts. In this case unrecognized spreading depression was elicited by electrical or chemical stimulation just rostral to the "motor" area in the macaque's precentral gyrus. After a matter of minutes movement elicited by stimulation of the "motor" cortex was abolished for 10 minutes or so, while reflexly elicited movement was unaffected. The idea was subsequently developed that a special strip, "area 4-S," functioned to suppress hyperkinetic tendencies, and the concept was furthered by the discovery of monosynaptic connections between this area and brain stem regions known to inhibit reflex action. The diagrams then showed "4-S" as suppressing hyperreflexia via the brain stem, neglecting the latency of minutes required for operation of this supposedly monosynaptic connection and its initially observed lack of effect on reflex action! Such nonsense illustrates the dangers of schematizing confirmatory evidence only, while neglecting contradictory or puzzling data.

Applied gradients. Efforts to assay the significance of the electrically polarized condition of the cortex have involved altering the transcortical potential artificially. Rather low intensity currents have pronounced effects on the polarity of evoked potentials, but not necessarily on the response of many of the subjacent neurons (Figure 2, Part II). Surface anodal polarization has the effect of increasing the negative component of evoked potentials and diminishing the positive component. This may be explained by assuming that the current hyperpolarizes apical dendrites and to some extent concurrently depolarizes the deeper lying cell bodies. EPSPs near the surface would thus be large because of the augmented membrane

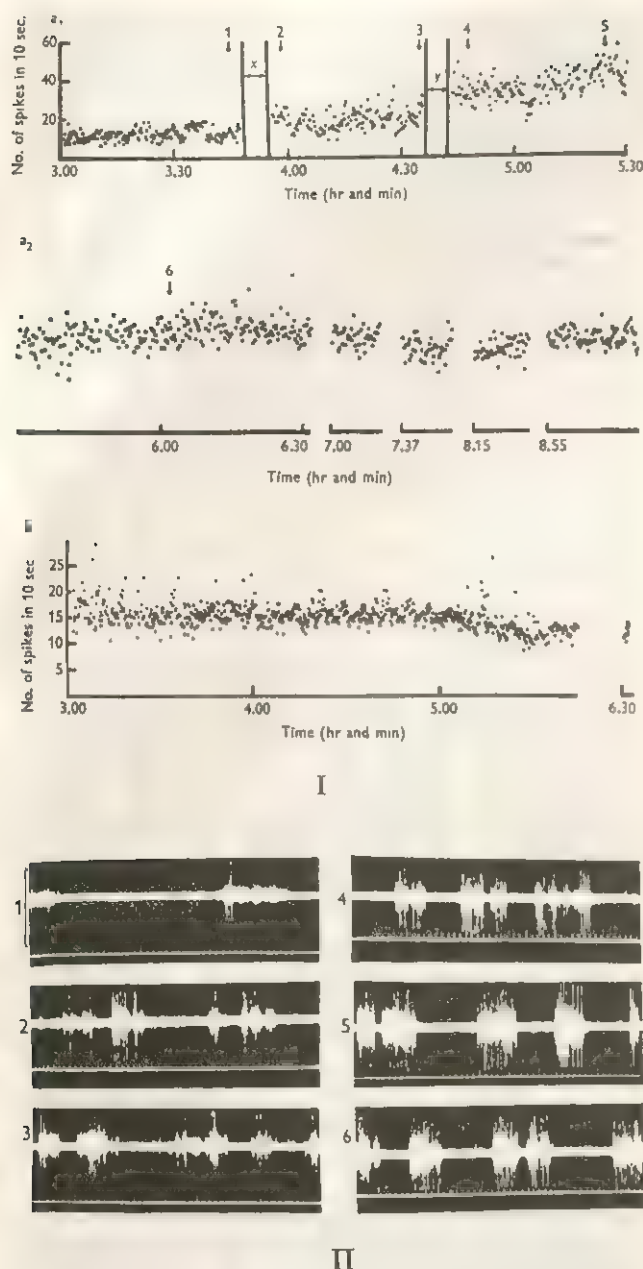

FIGURE 6. *I*, enduring effect of local polarization through a micropipette upon background activity of single neurons. Recorded 0.5 mm. beneath surface of somatosensory cortical representation of forepaw in rat under urethane anesthesia. At *X* and again at *Y* 0.25- μ amp. anodal current was passed for 10 minutes. Elevation in number of spikes per 10-second period was maintained for several hours (*a*₁ and *a*₂ continuous). *b*, another preparation, in which no polarizing current was passed and activity remained constant for several hours, even as judged on an expanded ordinate scale. *II*, actual records (1-second samples) taken from experiment in *a*₁ and *a*₂ at times indicated by numbers. Note that both the bursts per second and the number of spikes per burst increases. Vertical calibration, 0.5 mv. (From Bindmann, L. J., Lippold, O. C. J., and Redfearn, J. W. T. The action of brief polarizing currents on the cerebral cortex of the rat (1) during current flow and (2) in the production of long-lasting after-effects. *J. Physiol.*, 172: 369, 1964.)

potential and produce a greater negativity as recorded at the surface, and their depolarizing action in the deeper layers, which produces surface positivity, would be concurrently diminished; correspondingly IPSPs in the depths, which produce surface negativity, would be augmented, etc. The converse argument holds for the augmentation of positive components by surface cathodal polarization.

With stronger currents the excitability of PT cells can be altered, surface anodal polarization producing depolarization and excitation. The effects on non-PT cells are more variable, some responding to much lower currents than do PT cells, some being hyperpolarized by surface anodal polarization, and 40 per cent remaining uninfluenced.

It is difficult to say whether the normally existing D.C. potential gradient across the cortex has significant influence on the function of the cortical elements. It is likely, however, that the potential is only a reflection of the functional conditions of the subjacent cortical cells rather than a mechanism for their control or integration, the same considerations applying here as in the discussion above concerning the role of dendrites. In some instances local changes of metabolism or perhaps intercellular relations can apparently be altered by very minimal and discrete polarization (Figure 6). Such effects endure for extraordinary periods of time and are of great potential interest in their possible relations to mnemonic processes. The phenomenon (Figure 6) remains unexplained, however, and so far no known natural occurrences of this sort have been encountered.

Spontaneous Activity

Correlation with spike discharge and behavior. Except under conditions of the very deepest narcosis or asphyxia, continued electrical oscillations can be recorded from all cellular regions of the nervous system. The amplitude and frequency of these oscillations vary greatly depending upon the functional state and region of the brain. Each region has a characteristic pattern so that, for instance, the cerebral cortex can be divided into sectors having a particular variety of background rhythm and wave form, and the sectors correspond closely with cytoarchitecturally differentiable areas.

As a general rule, low voltage, fast (LVF) patterns correspond with a state of alertness and increased neural activity, while high voltage, slow (HVS) patterns are correlated with relaxation or reduced awareness and, in some respects, with a diminished level of neural activity. It is difficult, however, to press such general formulations since important and often puzzling exceptions are common. Among the most interesting is that during the rapid eye movement, LVF stage of sleep the electrical patterns of spontaneous activity in the neocortex are essentially indistinguishable from those of a fully alert individual even though, in cats at least, the state of sleep is demonstrably deeper than during stages with HVS activity. The converse of this paradox is seen with human patients having generalized background EEG pat-

FIGURE 7. Recruiting responses and their lack of behavioral effect. **A**, recruiting response recorded from subdural electrode over inferior premotor area in alert human patient during stimulation in the region of nucleus centrum medianum at 8 per second. Note typical quick increment in the response and slow decrement with continuing stimulation. Other subjective or objective changes were not apparent. Calibration, 100 per second, 100 μ V. **B**, squirrel monkey making learned movement of lever pressing (deflections labeled "CR" in bottom line) to avoid shock the imminence of which is signalled by intense, bilateral stimulation of n. centrum medianum. Movement made with right hand for which the cortical representation lies close to electrode LC (inset) in the center of area ansum. Movement made with left hand for which the cortical representation lies close to electrode LFA. Note symmetry and lack of it between the two hemispheres for various loci, indicating that while recruiting is a "diffuse" response, it is by no means global. Large, slow deflections occurring simultaneously are artifacts caused by animal's movements. Monkey could also respond when stimulation was one third the intensity shown and recruiting responses were not produced. (Part A is from Houseman, E. M., and Purpura, D. P. Electrophysiological studies of subcortical-cortical relations in man. *EEG Clin. Neurophysiol.*, 15: 20, 1963. Part B is from Peci Saavedra, J., Doty, R. W., and Hunt, H. B. Conditioned reflexes elicited in squirrel monkeys by stimuli producing recruiting responses. *EEG Clin. Neurophysiol.*, 19: 492, 1965.)

terms of 3 per second for many years without apparent impairment of alertness or mental functioning. Such dissociations between the expected EEG pattern and behavior can be produced by lesions in cats. For instance, following loss of the posterior hypothalamus a fully developed alerting reaction in the EEG (transformation from HVS to LVF patterns) can still be produced by electrical stimulation of the mesencephalic reticular formation, but despite this the animal shows no behavioral alteration in its comatose state. Conversely, with small lesions in the mesencephalic reticular system attentive behavior may be recovered despite the persistence of HVS, patterns. Absence of behavioral correlates is also common for evoked potentials. Thus the exceedingly high amplitude, slow potentials of the recruiting response (Figure 7) produce no subjective changes in man nor any *prima facie* disturbance in a monkey's performance of simple, learned acts the control of which is importantly influenced by the cortical areas engaged in the recruiting response. A similar case arises in cats that are wholly unable to detect stimulation limited to the largest afferents from muscle spindles even though the stimuli evoke prominent potentials in sensorimotor cortex. It is apparent, then, that in certain instances the gross electrical activity of the brain is an astonishingly poor indicator of its functional state or capacity.

The explanation is to be sought in the relation between the oscillations recordable from the surface and the spike discharge of neurons within the cortex (Figure 2). It is only the all or none discharge of the neuron, propagated down the axon, which is the *sine qua non* of neural integration or which can be expressed in behavior. Because of their brevity and usual lack of synchrony the spike discharges produce only the most minimal or no detectable change in the surface record. The latter must thus originate primarily from longer duration action, mostly in dendrites, which all evidence equates with postsynaptic potentials. The correlation between the EEG or evoked potentials and the functional output of the cortex will thus depend upon the degree to which EPSPs and IPSPs, variously synchronized among the multitudes of cortical neurons, reflect significant control of the spike discharges relevant to the system being studied (Figure 2). That the significant neural action may be impossible to infer from the surface record is readily illustrated with findings on the behavior of PT neurons in macaques during sleep with HVS patterns, sleep with LVF activity, and wakefulness. The EEGs in the latter two conditions are scarcely distinguishable, and the over-all frequencies of discharge in PT neurons are roughly similar, about 12 per second, compared to 6 per second for HVS sleep. The pattern of discharge for wakefulness, however, is entirely different from that in LVF sleep. In the latter, interspike intervals less than 10 milliseconds are 3 times more frequent than in the former, and the discharge is clustered into bursts, in striking contrast with the smoother temporal distribution during wakefulness. Non-PT cells, encountered adjacent to the PT cells, have still different characteristics in their pattern of discharge in the three conditions.

Origin. Intracellular records from neocortical neurons display constant fluctuations ranging up to sev-

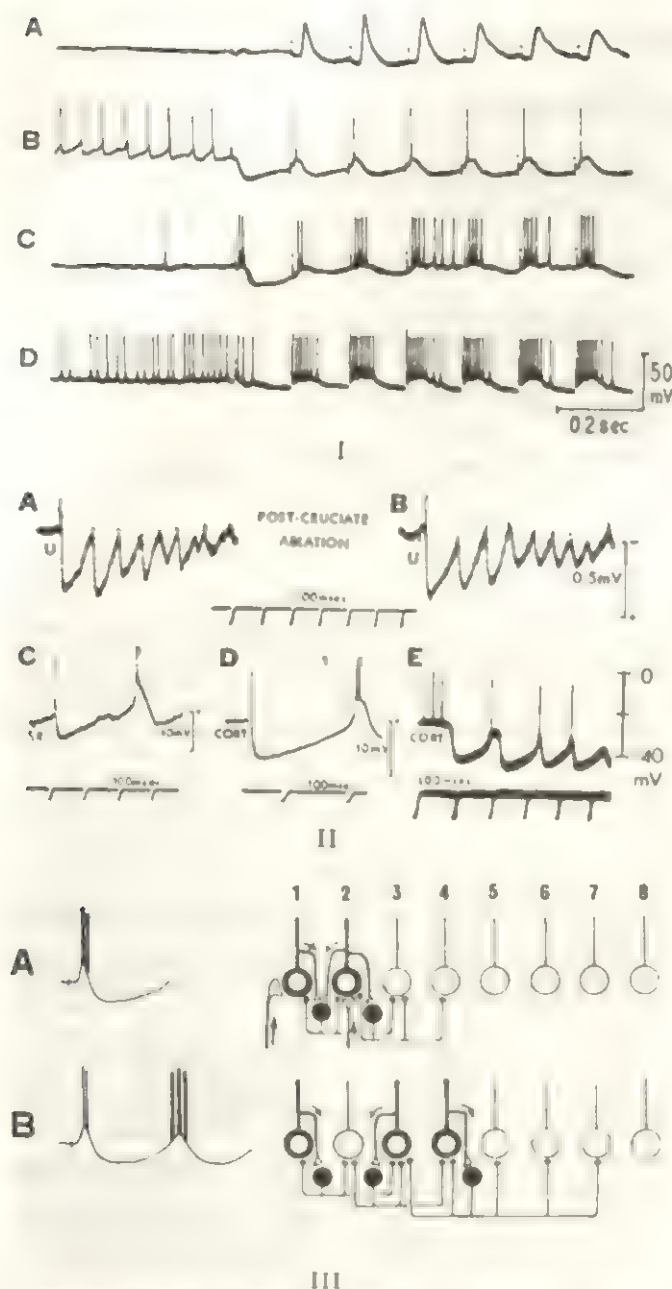

FIGURE 8. Role of IPSPs in generation of rhythmic activity. *I, A*, surface-negative recruiting responses (see Figure 7) recorded from "motor" cortex in cat during stimulation of n. centrum medianum at 7 per second; *B* to *D*, intracellular records from various thalamic cells recorded in this same animal during such stimulation. *B*, ventral anterior thalamus; *C*, ventrolateral; *D*, intralaminar region. It is apparent that the stimulus evokes a moderate, early EPSP in all these cells, followed by a pronounced IPSP which limits further excitation until its termination, thus locking all the affected cells in phase. *II, A* and *B*, rhythmic response of n. ventralis posterolateralis (VPL) (somatosensory "relay" nucleus) to single shock applied to ulnar nerve in cat under Nembutal anesthesia. Removal of all responding somatosensory cortex leaves thalamic response unchanged (*B*), thus demonstrating its thalamic origin. (The cuneate nucleus sends only a single volley up the medial lemniscus under these conditions.) *II, C* and *D*, prolonged IPSP and subsequent depolarizing overshoot or EPSP leading to second discharge of cell in VPL following a single shock to radial nerve (*C*) or to somatosensory cortex (*D*). *II, E*, same

eral millivolts and having all the characteristics of postsynaptic potentials. Analysis of their frequencies shows them to be identical with those of the EEG. Recorded extracellularly with two microelectrodes 30 to 50 μ apart the fluctuations are seen to be very local events, as expected of postsynaptic potentials (PSPs). The amplitude of these fluctuations seen in extracellular records, or intracellularly in glia, is only about one tenth that recorded intracellularly in neurons, and the recorded activity must therefore be generated in the neurons. The correlation between the EEG recorded from the cortical surface and the intracellularly recorded PSPs is understandably very poor. If each of the 50,000 neurons beneath the recording electrode had only 100 synapses which fired only once per second, 5,000,000 PSPs per second would be generated.

Since at rest or during HVS sleep rhythms of moderately high amplitude, rhythmic potentials can be recorded from the surface, considerable synchrony in the PSPs must be inferred on such occasions. The mechanisms which control the degree of synchrony are not entirely clear. As discussed in Section 2.6 and illustrated in Figure 8, recurrent inhibition has an important role in this connection. The protracted and widely ramified inhibition from the recurrent collateral system serves to modulate the activity of a large number of neurons and bring their excitability cycles into step. If these neurons are subjected to excitation just as the IPSP is subsiding, they will all fire in phase and further ramify the recurrent inhibition. Thus stimuli in the range of 6 to 10 per second, having intervals which correspond to the duration of the IPSPs, are uniquely effective in synchronizing cellular discharge and EEG rhythms at this frequency.

Since the first few such stimuli will bring more and more neurons into the system of synchronized discharge, the responses increase in amplitude and are called "recruiting responses" for the case of surface-negative waves produced by stimulation of the thalamic components of the centrencephalic system (Figure 8, *Part I*, Figure 7), and "augmenting responses" for the surface-positive waves produced by stimulation of the thalamic relay nuclei (Figure 8, *Part II*). The recruiting responses are of particular interest because of their similarity to the spindling activity which occurs during sleep or light barbiturate anesthesia. Higher frequency stimulation within the pertinent nucleus or imposed upon it from artificial or natural engagement

in another cat, on slower time scale showing IPSPs and rhythmic thalamic action following single cortical stimulus. Thus, antidromic stimulation (seen intracellularly in *D*) generates rhythmic effects suggesting the schema in *III*. In *A*, afferent volley discharges cells 1 and 2, with recurrent collaterals which excite inhibitory interneurons (solid black); electrical record of this stage being shown at left. In *B*, cells 3 and 4, recovering from inhibition also discharge, in addition to repeat discharge by 1, further elaborating the process and yielding further portion of electrical record at left. (*Part I* is from Purpura, D. P., and Shofer, R. J. Intracellular recording from thalamic neurons during reticulocortical activation. *J. Neurophysiol.*, 26: 494, 1963. *Part II* and *Part III* are from Andersen, P. Rhythmic 10 sec activity in the thalamus. In *The Thalamus*, D. P. Purpura, and M. D. Yahr, editors, p. 143. Columbia University Press, New York, 1966.)

of systems afferent to it tends to disrupt the synchrony and return the cortex to LVF activity. While the cortex probably has recurrent inhibitory processes which participate in the development of its various rhythms, the control of these patterns appears to be exerted predominantly by, and certainly requires the presence of, subcortical systems.

Hippocampal theta rhythm. The theta rhythm of the hippocampus is somewhat instructive in the understanding of certain aspects in the generation of EEG activity. This sinusoidal, high amplitude pattern, 4 to 7 per second, is particularly well developed in rabbits and also occurs in cats, but is essentially absent in primates. The same stimuli which produce LVF activity in the neocortex concurrently induce the theta rhythm in the hippocampus. In other words, stimulation of the mesencephalic reticular formation is highly effective in producing theta activity, and to some degree the frequency of the theta rhythm is proportional to the intensity of the reticular stimulation. With very intense stimulation, however, a second, faster rhythm, 20 to 40 per second, is superimposed upon the theta rhythm. The brain stem origins of these two patterns appear to be separable to some degree so that stimulation of the central gray, medial hypothalamus, or preoptic area induces theta activity whereas the hippocampal fast activity arises from stimulation of the lateral hypothalamus or medial septal area. The phase relations (see below) of the fast versus theta activity appear to be the same across the layer of pyramidal cell bodies, but the two follow different pathways. Lesions of the medial septal area (Figure 4 in Section 2.8) irreversibly abolish all theta activity without affecting the fast patterns. Lesions of the entorhinal area, on the other hand, have no effect on the theta rhythm, while observations are apparently lacking for their effect on the faster rhythms.

The importance of the medial septal area in the generation of theta activity is seen in two other facts. First, stimulation here with high frequencies abolishes the theta rhythm, while frequencies of 4 to 30 per second evoke potentials in the hippocampus somewhat resembling the theta rhythm which they disrupt. Second, large cells in the medial septal area and nucleus of the diagonal band of Broca (Figure 7 in Section 2.8) discharge bursts precisely correlated with the theta waves. The origin of the burst activity in these cells is unknown, but it seems certain to provide the essential component for generating the theta rhythm in the hippocampus, being projected via the fornix onto the dendrites of the pyramidal cells.

The theta activity arises as an oscillating dipole across the somata of the hippocampal pyramidal cells. One pole arises from EPSPs in the apical dendritic layers (Figure 3 in Section 2.8), but the origin of the activity in the axonal-basilar dendritic layers is not clear. A null point exists and apparently lies at the level of the cell bodies, thus indicating that the somata probably do not participate actively in generation of the rhythm. The existence of the null point proves that the oscillation and phase shift does not involve propagation of activity up or down the dendrites. The null point at the level of the somata is puzzling, however, as most hippocampal pyramidal cells fire in bursts phase-locked with the theta rhythm. Since their discharge produces recurrent inhibition (Section 2.6), positivity should appear in the region of the cell bodies. Obviously the evidence is insufficient to demonstrate precisely how the theta rhythm is produced, but it is certain that it requires afferent input from the medial septal area and that it involves nonpropagating PSPs in dendrites.

The hippocampal pyramidal cells are peculiar among central neurons in having a very prominent depolarizing after-potential with no hyperpolarizing after-potential. This might arise because of the tight glial investiture of these cells which leaves such a

small extracellular space that the K^+ leakage during a spike potential could significantly change its extracellular concentration, thus producing depolarization. In any event with this depolarizing after-potential the hippocampal pyramidal cells tend to fire in bursts of two or three spikes and are particularly prone to abnormal, seizure discharge (a fact not without clinical significance; see Section 2.8). The possible relation between this predilection toward burst discharge and the existence of the theta rhythm remains to be investigated.

One last problem is the phase lag in the theta rhythm between one part of the hippocampus and another. The lag is systematic, suggesting a propagation through the hippocampus at a rate of 0.03 to 0.04 m. per second. This is much too slow to be explained in terms of conduction velocities in afferents from the septum, and there is no evidence to support other possible explanations. In cats the wave is initiated usually from the dorsal hippocampus and progresses towards the entorhinal area (Figure 4 in Section 2.8), but during the period of a learned approach decision the direction of this propagation is reversed.

Control of Neocortical Activity: The Centrencephalic System

Isolated cortex. Just as generation of the theta rhythm of the hippocampus is dependent upon afferents from the septum, all normal EEG rhythms of neocortex require afferent support from subcortical areas. To what degree the normal patterns are merely imposed upon the cortical system and to what degree they arise from cortical modulations of afferent input is by no means clear. It is thus of interest to know what capabilities are possessed by the cortex alone.

As mentioned above, the propagation of direct cortical responses or spreading depression is essentially the same in undercut as in intact cortex. Photically evoked potentials also can propagate at 1 to 2 m. per second throughout a slab of "visual" cortex isolated for about 10 mm. by destruction of the white matter except at one end. Since such propagation can occur into partially isolated cortex, total isolation is required to study cortical capabilities per se. Even total isolation will have varying effects depending upon the size of the isolated slab, whether "U" fibers remain, and the degree to which success is achieved in preserving the vascular supply (which enters only through the pia mater). Obviously the cortical denervation will be much more severe when the "U" fibers are cut, and in such instances as many as one third of the cortical neurons degenerate. This type of preparation has not been adequately examined for spontaneous activity over long periods without interference from anesthesia and circulatory disturbances. In slabs 10×5 mm. or larger in which "U" fibers are preserved there is only a minor loss of cells, and considerable electrical activity returns. The rhythm is never normal, but many components of normal activity occur briefly. The records are characterized by sporadic activity, bursts of slow waves or spikes alternating with periods of silence.

In human patients such sporadic activity remained relatively constant at 15 to 30 bursts per minute for at least 15 months from the moment of isolation of large areas of frontal cortex. Isolated cortex can produce the major forms of pathological electrical

activity such as 3 per second spike and wave patterns, seizure discharge, and after-discharges. Indeed a supersensitivity of denervation occurs within 2 weeks so that seizure discharge is much easier to induce with electrical or chemical stimulation in chronically isolated than in intact cortex.

Centrencephalic system. Normally the most important contribution to the character of the background activity of the EEG arises in the centrencephalic system. This system is more a functional concept than an anatomical entity. It was originally conceived primarily as a diencephalic system regulating and accounting for the bilateral symmetry in the electrical activity of corresponding cortical areas of the two hemispheres and effecting the general coordination of background activity of the cortex. Since these regulatory mechanisms also involve medullary, pontine, and mesencephalic levels, the term "centrencephalic" has been enlarged to include these components. The functions of such a system obviously are not to regulate electrical patterns per se but to support some aspect of the total neural process. These functions are still being defined, but they are related to the control and processing of sensorial input; to attention, awareness, sleep; and perhaps to the transmutation of neural activity into the unity of consciousness. The centrencephalic system can thus be loosely defined as a functionally related system of neurons, for the most part found near the midline and coursing from obex to septum, controlling sensorial input and thereby controlling attention, alertness, and their electrophysiological manifestations. How exact the correspondence may be between the centrencephalic system and neurons of the "reticular" type (Figure 2 in Section 2.5) remains to be investigated.

Mesencephalic reticular formation: Isolated forebrain. In many respects the hub of this system is the mesencephalic reticular formation since it is here that lesions or stimulation produce the most global effects. Cells here are commonly activated from a variety of sources, and their background rhythm is steady in contrast to cells in thalamic relay nuclei with background which consists usually of grouped discharges. Electrical stimulation of relatively high frequency, but low intensity, produces in resting animals both behavioral arousal and a transition from HVS to LVF patterns in all cortical areas. It is presumed that a natural stimulus which produces such alerting does so largely through collateral systems which account for the multimodal excitability of the reticular neurons. However, the cerebral cortex also possesses the capability of influencing this arousal system, and it is not at all unlikely that a part of the arousal process normally involves a loop through cortex and then to the mesencephalon to effect a widespread reaction. In man the telencephalon may actually have primacy in the phenomenon of consciousness. In hemispherectomized patients intracarotid injection of Amytal on the side of the remaining

hemisphere produces an immediate loss of consciousness, and angiography indicates that the Amytal should not reach the mesencephalon in significant quantities. Moreover, injection of Amytal into the vertebral circulation in other patients, while producing vertigo, oculomotor, facial and lingual paralysis, and loss of pupillary light reflex, has no influence on consciousness. This is definitely paradoxical since midbrain lesions produce coma in man as well as animals. It probably means that the mesencephalic reticular system is not so sensitive to barbiturates as is believed and that it simply remains unaffected by the brief exposure to intravertebral Amytal, as is also the case with the auditory, respiratory, and cardiovascular systems.

Bulbar and pontine systems also exert important influences, predominantly inhibitory, upon the mesencephalic component. If the medullary influence, probably arising near portions of nucleus solitarius, is removed by a section at the caudal border of the pons, stimulation of the mesencephalic reticular system yields a more protracted arousal than previously. Cats with brain stem transected at midpontine levels maintain an almost constant LVF activity in neocortex for days. The latter result is somewhat unexpected since the caudal pons seems to be the site controlling the appearance of LVF activity during the rapid eye movement phase of sleep, but evidently a tonically active system promoting HVS activity must also lie caudal to the midpontine transection. The LVF activity of the midpontine preparation is associated with seeming alertness rather than deep sleep since a "midpontine" cat tracks objects visually and can learn and perform conditioned reflexes, e.g., pupillary dilatation to photic stimulation using electrical stimulation of the posterior hypothalamus as unconditional stimulus.

Medial lesions of the rostral pons or mesencephalic reticular formation produce coma and continuous HVS activity, neither of which within the first few postoperative days can be interrupted. This certainly dramatizes the cardinal importance of this area of the brain and the diffuse paths traversing it. The meaningful operation of the nervous system is brought to a halt despite the fact that all the major afferent and efferent systems are intact and sensory stimuli readily evoke potentials in neocortex. The condition is not permanent, however, and within a few weeks after such a bilateral lesion a cat can again acquire simple conditioned reflexes and display many aspects of normal behavior. Even with total transection and elimination of any connection between fore- and midbrain, normal LVF activity gradually returns in the isolated forebrain. Such recovered preparations have LVF activity for hours at a time as well as periodic episodes of HVS activity lasting about 1 hour, showing no correlation either with electrical activity of the brain stem or usually with the behavior controlled by the brain stem. In some instances of intense arousal by painful stimuli, sneezing, or defecation, however, the forebrain HVS patterns are interrupted, suggesting a humoral effect. Apparently no such interruptions occur during episodes in brain stem activity which are normally associated with the rapid eye movement phase of sleep. HVS episodes in the forebrain can be interrupted by olfactory stimuli, but not by visual stimuli, suggesting that the mesencephalic reticular system may be es-

sential for arousal via the visual system. Otherwise the electrical activity of the forebrain remains the same following coagulation of both optic disks and aspiration of the olfactory bulbs. The sustained LVF activity in the isolated forebrain requires the presence of the diencephalon.

The gradual assumption by the diencephalon of the ability to engender LVF activity in neocortex proceeds unilaterally, as can be shown by serial hemisections (Figure 9). The nature of this compensatory reaction is unknown. It seems that normally arousal to electrical stimulation of the thalamus proceeds via posteriorly projecting paths through the posterior commissure and pretectal area, for with acutely produced lesions the arousal reaction does not survive isolated transection of this path posterior to the point of thalamic stimulation.

Diffuse thalamocortical projection system. The thalamic component of the centrencephalic system inevitably emerges as existing primarily to originate sleep spindles and recruiting responses in neocortex since it is the intensive study of these phenomena that has generated most of the knowledge about it. Unfortunately, even this knowledge is frustratingly inadequate since the anatomical paths by which centrencephalic influences reach the cortex from either thalamus or midbrain cannot yet be specified precisely.

Study of these systems began with the finding that in cats under very deep barbiturate anesthesia stimulation of the sciatic nerve produced, in addition to the primary response of 8- to 10-millisecond latency localized in contralateral somatosensory cortical areas, a secondary response with a latency of 30 to 80 milliseconds engaging the entire cortex bilaterally. A hemisection of the brain stem at the intercollicular level ipsilateral to the primary response abolished the latter but did not change the distribution of the secondary response. The secondary response in such an instance must represent a double crossing, once below the level of the hemisection and again above it from the intact to the deafferented hemisphere, and is obviously distinct from direct sensory pathways. This second crossing was demonstrated to be via the corpus callosum. On the other hand, electrical stimulation of medial thalamic structures can produce recruiting responses with a rather wide bilateral distribution. That the bilaterality does not arise simply from physical spread of stimulating current across the midline is shown by the fact that latencies of the contralateral recruiting responses are about double those of the ipsilateral response, e.g., 40 versus 20 milliseconds. Such findings gave rise to the concept of a diffuse thalamocortical projection system, but its very diffuseness together with its lability makes it very difficult to study. Several points bear emphasis. First, this system exerts its influence on the cortex independently of the thalamic relay nuclei of the specific sensory systems. Its diffuseness and nonspecificity are apparent only in certain circumstances. The location of thalamic regions from which recruiting responses can be obtained are very restricted since movement of an electrode by 0.5 mm. makes the difference between presence and absence of recruiting responses. Furthermore, slight movements of the stimulating electrode often make great changes in the distribution of the response (Figure 7B). In more lateral thalamic areas from which recruiting responses can be induced, the responses are almost entirely unilateral.

Bilateral symmetry: corpus callosum. Thus, while the thalamic component of the centrencephalic system can operate to achieve a bilateral symmetry in neocortical electrical pat-

FIGURE 9. Unilateral reorganization of tonic, background EEG activity following hemisection of the mesencephalon. *A*, The left mesencephalon was transected under ether anesthesia a few hours earlier, and bursts of high voltage, slow EEG activity predominate in records from the left hemisphere. At such times intense noise can produce arousal reactions (not shown) in the affected hemisphere, but they are much shorter in duration than in the "intact" hemisphere. *B*, Seven days later, symmetry was restored in the EEG, and low voltage, fast activity persisted equally in both hemispheres. The right mesencephalon was then transected (producing a *cerveau isolé*) and it was found (*C*) that the low voltage, fast pattern of the previously transected side was maintained by some reorganization intrinsic to that hemisphere rather than from augmented control by the originally "intact" hemisphere, since the low voltage, fast pattern was now maintained on the left in the face of high voltage, slow patterns on the right. Electrode loci: *F*, frontal; *P*, parietal; *O*, occipital. (From Cordeau, J. P., and Mancia, M. Effect of unilateral chronic lesions of the midbrain on the electrocortical activity of the cat. *Arch. Ital. Biol.*, 96: 374, 1958.)

terns, there are indications that its contributions in this regard are not particularly strong. Besides the absence of thalamic transfer of the secondary response, of compensation to chronic hemisection, and of recruiting responses from lateral loci, it is also seen that section of the corpus callosum and anterior commissure greatly reduces the degree of bilateral symmetry in the EEG. Thus, these latter structures also function in correlating the electrical activity of the two hemispheres. Since the corpus callosum in man has about 200 million fibers, roughly 2 per cent of the cortical neurons send fibers through it. The density of this projection varies greatly from one cortical area to another. The primary visual projection area, for instance, has no direct interhemispheric connections and, in primates at least, can communicate with its corresponding contralateral half to achieve unity in an otherwise split visual field only via callosal connections passing between prestriate areas. Similarly, in cats it has been demonstrated that transfer of somatosensory information from one hemisphere to another proceeds only through specialized cortical areas. In at least some instances the same cortical points which intercommunicate via the corpus callosum also do so via a much slower pathway traversing the mesencephalic reticular system. Thus, an electrical pulse applied to such a cortical point elicits an initial response, which is a mixture of orthodromic and antidromic effects, beginning in the homotopic cortical area within 1 to 2 milliseconds; and a second more widely distributed potential, the interhemispheric delayed response (IDR), with a latency of 40 to 65 milliseconds. The IDR is very labile, is sensitive to anesthesia, and can also be produced by midbrain stimuli. It is unaffected by sectioning the corpus callosum, psalterium, anterior and posterior commissures, and the entire diencephalon. Some degree of bilateral symmetry in cortical activity can still be observed in such "split brain" preparations.

In summary, it can be concluded that the symmetry

in the electrical activity of the two hemispheres is maintained by three systems: the commissural, the medial thalamic, and the mesencephalic reticular, the contributions of which undoubtedly fluctuate according to a variety of circumstances.

Cortical influence on the centrencephalic system. The neocortex exerts continuous control over the thalamic and mesencephalic systems. For instance, extirpation of neocortex greatly augments the background activity in nucleus centrum medianum and doubles the amplitude of responses seen there to somatic stimulation. Similarly, decortication enhances and widens the distribution of photic responses seen in the thalamus outside the lateral geniculate body. It has also been reported that the brain stem structures no longer display HVS background activity following total decortication.

Stimuli applied to certain restricted areas of neocortex in macaques, excluding area striata, middle temporal gyrus, and frontal pole, evoke potentials and alter conduction in the mesencephalic reticular formation. The presence of potentials in the mesencephalic reticular formation following somatosensory stimuli seems to be specifically under control of the second somatosensory area (SII) since local cooling here abolishes the response in the mesencephalon while leaving that at "primary" somatosensory cortex (SI) unaffected. Cooling of SI has no effect until the responses in SII are reduced.

Control of Sensory Systems

By recording from a single fiber in the human radial nerve it can be shown that a brief, 5° displacement of a hair on the hand produces a single nerve impulse; yet such displacement can be detected subjectively. It is obvious, however, that not all such displacements yield a subjective reaction and, indeed, the nervous system must be bombarded with tens of thousands of impulses each second which remain without effect unless "attention is focused" upon them. Within the past decade or so it has become possible to specify a number of mechanisms available to the nervous system to perform this selective focusing.

The first of these is the control exerted at the peripheral end organ or the early synaptic stations in the central nervous system. The gamma-efferent system provides a striking example since in this instance the nervous system can actually initiate its own input over the muscle spindle afferents in the absence of any peripherally imposed change. This is a bad example, however, for subjective sensation *per se*, since neither cat nor man can perceive stimulation limited to these afferents. For perceptually effective somatic afferents the control is exerted at the first synaptic relay either in the dorsal horn of the spinal cord, in the trigeminal complex, or in nucleus gracilis or cuneatus (Figure 9 in Section 2.6). Presynaptic inhibition of discharge to afferent input can be obtained in all these regions via the pyramidal tract following stimulation of sensorimotor cortex. Stimulation in the medullary or mesencephalic reticular systems can also depress transmission of somatosensory information at these first central stations. These centrencephalic connections may be responsible for the ability of clicks or flashes to affect the excitability of cells in the chief sensory trigeminal nucleus.

Activity in the olfactory bulb is controlled by systems in the prepiriform cortex, olfactory tubercle, and the other ol-

factory bulb which sends fibers through the anterior commissure. Stimulation of these centrifugal fibers depresses background and evoked activity in the bulb, and isolation of the bulb enhances its background and responsivity.

Centrifugal fibers arising in the superior olive form the olivocochlear bundle, three fourths of which decussate near the floor of the fourth ventricle. It passes into the cochlea to form large endings upon the hair cells where they contact the afferent fibers. The olivocochlear bundle constitutes about 1 to 2 per cent of the fibers of the auditory nerve. A similar system, probably arising in the lateral vestibular nucleus and not decussating, passes into the labyrinth, where the efferent fibers seem to contact the afferent fibers. Stimulation of the olivocochlear bundle depresses the cochlear microphonic and thus reduces auditory input. The response in the cochlear nuclei is in turn affected by a system running from the ventral temporal cortex through the medial aspect of the medial geniculate nucleus, the ventral part of the inferior colliculus, and along the medial edge of the nucleus of the lateral lemniscus.

The retina is also supplied with efferent fibers which end in the layer of bipolar cells and can alter or initiate responses in retinal ganglion cells. The function and even the origin of these fibers are unknown, although stimulation in the mesencephalic reticular system can evoke the efferent effects. In the pigeon the retinal efferent fibers arise from the isthmo-optic nucleus in the caudal midbrain. They constitute about 1 per cent of the optic tract and seem to form axosomatic endings on amacrine cells.

A most important point of control in the visual system is the lateral geniculate nucleus. In primates the mesencephalic reticular system has such powerful influence here that it sometimes appears almost literally to turn the visual system on or off (Figure 4, Part II)—"gating," as it is called in engineering parlance. Such control, in fact, may be the *raison d'être* for thalamic "relay" nuclei; for there is nothing to be gained from a 1:1 relay, and the pyramidal system demonstrates that interruption of long central pathways is at least not a necessity. Be that as it may, a single pulse applied to the mesencephalic reticular formation in monkeys produces presynaptic inhibition lasting about 30 milliseconds for both parvo- and magnocellular elements, followed by facilitation for 100 milliseconds or more. Such stimulation also has the behavioral effect of improving the performance of monkeys in perceiving tachistoscopically presented stimuli. Lesions in this mesencephalic area have such catastrophic effects that it is difficult to study the resultant visual deficiencies, but there are a number of indications that they are severe. The multimodal inputs of the mesencephalic reticular system allow influences to be brought to bear upon the visual system from many other sources and no doubt accounts for such findings as those in the cat where, under conditions of heightened excitability, potentials can be evoked in the lateral geniculate nucleus and its neurons discharged by touching the paws.

It might be suspected that one of the major purposes of this midbrain control of the visual system would be to supply a "blanking" of vision while the eyes are in motion, or to adjust the visual input relevant to the position of the eyes. If so, these effects do not seem to be supplied by collaterals of oculomotor neurons, since their stimulation is without effect, but they may instead possibly be supplied by the systems which control eye position. During the rapid eye movement stage of sleep presynaptic inhibition is applied to the lateral geniculate nucleus at the same time that the eyes are moved, and there is a close correlation between spikes appearing in the pontine nuclei, lateral geniculate nucleus, and visual cortex. Thus, centrencephalic control of the visual system can originate even at pontine levels, a fact possibly to be anticipated from the connections between the vestibular and oculomotor systems. In cats the vestibular effects are very well developed since all neurons which can be isolated by microelectrodes in the "visual" cortex can be influenced or discharged by moderate vestibular stimulation. The latencies for the effect range from

25 to 200 milliseconds compared with 8 to 20 milliseconds for responses in the vestibular projection area for these same stimuli. The effects at visual cortex may pass via the diffuse cortico-thalamic projection system since the vestibular stimuli do not affect neurons in the lateral geniculate nucleus. Stimulation of this thalamic system itself can discharge or inhibit 70 per cent of neurons isolated in the contralateral visual cortex of cats, mostly after latencies exceeding 25 milliseconds. During the various stages of sleep and wakefulness the excitability of the lateral geniculate nucleus and visual cortex in cats can vary independently, even in opposite directions. The visual cortical system is by no means passive in this regard since it in turn influences the excitability of neurons in the lateral geniculate nucleus and, probably via the superior colliculus, the mesencephalic reticular system as well. Corresponding experiments have not yet been done in primates, but preliminary information suggests that centrencephalic control is exerted predominantly on the lateral geniculate nucleus with only minimal influence on striate cortex.

The auditory system has been little studied in this regard, but arousal greatly increases potentials recorded in auditory cortex following electrical stimulation of the medial geniculate nucleus. For the somatosensory system there appears to be much less direct convergence of centrencephalic influences onto cortical neurons responding to somatic stimuli than is the corresponding case for neurons in the "visual" cortex responding to photic and thalamic stimuli. The same is true in comparing somatosensory areas with "motor" or "association" cortex; i.e., cortical neurons driven by stimulation of the ventrobasal complex are not usually discharged by stimulation of the diffuse thalamic projection system even though their response to the former may be altered (usually increased) by the latter. This relative ineffectiveness of centrencephalic control probably accounts for the stability of response in the non-PT cells of the cortical somatosensory system, as described above. The association areas, on the other hand, have a high degree of multimodal convergence and receive a powerful centrencephalic input. The middle suprasylvian gyrus of the cat is the best studied in this respect. Of the neurons isolated here 80 per cent respond to flashes, 50 per cent to clicks, 30 per cent to electrical stimulation of the paw, 50 per cent to stimulation of the lateral posterior nucleus (the thalamic projection nucleus for this area), 50 per cent to stimulation of nucleus centrum medianum, and 85 per cent directly to transcallosal stimulation; 40 per cent participate in the interhemispheric delayed response. Obviously each neuron tends to respond (with EPSPs or IPSPs) to input from many sources. In another series of experiments comparison could be made directly for the convergence of influences from the midline thalamus and specific thalamic projection nuclei. Convergence was found for 75 per cent of the neurons isolated in the suprasylvian association cortex, 41 per cent in motor cortex, and only 8 per cent for somatosensory cortex.

It seems reasonable to suppose that neurons receiving multimodal input are uniquely important in forming learned associations between stimuli. The prominence of multimodal representation in the centrencephalic system and this system's exceptionally powerful influence upon the multimodal systems of the neocortex seem likely to have some intimate relation to mnemonic processes.

2.8 LIMBIC SYSTEM

ROBERT W. DOTY, Ph.D.

Most of the great systems of the neocortex are concerned with the external world, its spatial properties and directionality. In striking contrast, the limbic system is concerned with the self. It controls exchange between the body and the external world and, through its command over the autonomic and endocrine systems, regulates the internal world. To these functions of preserving the individual, Nature has cunningly linked as well those of preserving the species. In achieving these ends, the limbic system serves as a repository for phylogenetically significant, instinctual behaviors. From its organization come such species-specific activities as feeding, drinking, defense-flight reactions, aggression, sexual and probably maternal responses, grooming, and temperature regulation. The stimuli associated with these behaviors are "motivational" in that the organism seeks or avoids them, and there is every reason to believe that it is the limbic system which assigns the motivational value to particular stimuli.

The effects of stimulating or ablating most neocortical areas are motivationally insignificant. Stimulation of the limbic system, on the other hand, often produces motivational effects (either avoidance or approach) of overpowering intensity, and lesions in the limbic system commonly effect a profound derangement of basic behavior. These principles can be illustrated with laboratory experiments, although they sometimes appear with almost equal clarity in clinical cases. The "elementary personality" of cats is unchanged by removal of all neocortex. So long as the subcortical limbic system (including hippocampus and basal ganglia) remains intact, decorticate cats

that preoperatively show aggressive resistance to handling of any kind continue to do so, whereas gentle animals still purr and stretch when petted after decortication. Gentle cats can be made permanently ferocious by lesions in the ventromedial nuclei of the hypothalamus while conversely, savageness disappears from intractable cats following bilateral amygdalectomy unless they are strongly provoked by painful stimuli. Amygdalectomy has similar effects even in such feral animals as the lynx, gray rat, or macaque; and following lesions in the homologue of the amygdaloid system of mammals, mallard ducks, normally extremely fearful, can be captured by hand.

With section of the optic chiasm and corpus callosum in macaques unilateral excision of the tip of the temporal lobe (including the amygdala) produces a fascinating situation. When the animal views the world with both eyes or with the eye connected to the hemisphere in which the amygdala is present, it displays the macaque's usual fearful-aggressive behavior towards man. However, when it sees only through the eye ipsilateral to the amygdalectomy, the monkey is without fear. It accepts man's presence calmly and only when handled does it show savage behavior. The monkey's attitude toward the external world is thus dependent upon the state of the limbic system in the brain with which he views it.

Such facts obviously have direct relevance to psychiatry and indeed to medicine in general. In man it can be verified that strong emotion accompanies the manifestations of activity in the limbic system, and disturbance of emotional balance is a frequent correlate of pathology in this system. In turn, the play of emotions or, what is probably the other side of the same coin, certain activity within the limbic system can alter the entire body economy. Psychosomatic medicine originates in this fact. The limbic system regulates digestion, renal activity, sexual cycles, basal metabolism, and the pressure, distribution, and composition of the blood. It thus provides or is the channel by which the mental self interacts with the body self; and its derangement may be expressed in body, mind, or both. A patient with abnormal functioning of the central visual system might fail to see certain colors, or in certain directions, or see nonexistent objects; with disease affecting the motor system he may be paralyzed, experience convulsions or incessant, purposeless movement; but one afflicted with pathology within the limbic system may suffer rage, unbridled fear, or some equally overwhelming, ineffable, and mysteriously distorted appraisal of the world and its relation to himself. In the latter circumstance he is psychotic. The pathological neural substrates of psychosis cannot yet be identified, but the evidence grows consistently stronger that they are to be sought primarily in the limbic system. Only 25 years ago a prominent text in neuroanatomy could with some truth comfort the medical student, perplexed with the in-

tricacies of the hippocampus or amygdala, that study of the limbic system had but limited application to the practice of medicine. With the appearance of neuroendocrinology such assurance has quietly subsided; and in its place may well be substituted the prediction that the psychiatrist of the future will be a neurologist specializing in disorders of the limbic system.

Anatomy

Limbic cortex. The term "limbic" is taken from *limbus* (border) and signifies the structures bordering the medial aspect of the hemisphere. These include temporal-insular, orbitofrontal, cingulate, and retrosplenial cortex (Figure 1). This limbic neocortex plus the hippocampal gyrus forms the hub of the system through and with which many other components of the system are connected.

The limbic cortex can be divided into four systems on the basis of thalamic projection nuclei and the afferent connections of these nuclei. (1) The hippocampal gyrus is allocortex rather than neocortex and has no known direct thalamic connection. It serves as the primary afferent channel into the hippocampus. (2) The orbitofrontal cortex is innervated by the magnocellular division of nucleus medialis dorsalis. The latter receives afferents from the piriform tract. Thus the orbitofrontal cortex has a rather direct relation to olfactory input. The magnocellular component of nucleus medialis dorsalis in primates also receives fibers from the fornix system. (3) Insular cortex receives fibers from n. ventralis anterior which in turn is innervated predominantly from the globus pallidus. (4) The cingulate gyrus receives fibers from the anterior thalamic nuclei. This is the most extensive of the limbic cortical systems, and the various anterior thalamic nuclei project to the entire expanse of the cingulate gyrus. The anterior thalamic nuclei are richly innervated by the mammillothalamic tract from the medial mammillary nucleus.

The posterior portion of the cingulate gyrus receives afferents from n. lateralis dorsalis, a nucleus that also has a rather heavy innervation from the fornix system. Thalamic input to the retrosplenial area in primates is not well known. This area adjoins directly upon the primary visual cortex (area striata) so it is perhaps not surprising that it receives afferent fibers from striate cortex and that neurons in the retrosplenial area can be discharged by photic stimuli. Other portions of the limbic cortex also receive fibers from and send them into "supralimbic" cortex. The cingulate cortices of the two hemispheres are interconnected via the corpus callosum; while the insular-temporal cortices are interconnected via the anterior commissure (Figure 2). Temporal cortex also projects upon the amygdala and, by fibers joining the fornix after penetrating the corpus callosum, probably upon the lateral septal nucleus. Efferent connections from limbic cortex to the corresponding thalamic projection nuclei have been described, as well as to the basal ganglia.

While not part of the limbic system in the sense of location, in terms of connectivity much of the rostradorsal convexity of the frontal lobe must be included. This is the cortex receiving

FIGURE 1. Medial view of hemisphere diagrammatically dissected to illustrate certain structures of the limbic system. *Parolfactory area* is roughly equivalent to the septal area. The *fasciola cinerea* is a small extension of the hippocampal system. (Reprinted with permission of The Macmillan Company, from Crosby, E. C., Humphrey, T., and Lauer, E. W. *Correlative Anatomy of the Nervous System*, p. 316. © The Macmillan Company, New York, 1962.)

projections from the extensive parvocellular portions of the medial dorsal nucleus. The parvocellular components have two major inputs: (1) large fibers which ascend from the ventromedial midbrain and ventral tegmental area of Tsai passing along the anterior border of the habenulo-peduncular tract; (2) large fibers arising in the medial septal nucleus of the diagonal band of Broca. Thus the primary input to the prefrontal cortex via the medial dorsal nucleus arises from areas which are part of the limbic system. These areas of the prefrontal cortex also join the limbic system in sending efferent fibers into putamen, claustrum, head of the caudate nucleus, the cingulum, and the periaqueductal gray.

A large band of fibers completely encircles the limbic cortex and serves as its major efferent and association pathway. Ventrally this fiber system is the uncinate fasciculus, forming a two-way connection between orbitofrontal and insular-temporal cortex. The predominant system, however, is the cingulum which runs a looping course above the corpus callosum medially within the white matter of the cingulate gyrus (Figure 1). It arises diffusely in the prefrontal cortex, exclusive of the orbital area, and, while fibers course in both directions within it, the greatest projection is from the rostral to caudal portions. Axons of pyramidal cells from cingulate cortex frequently branch, sending one collateral rostrally into septum or striatum and the other caudally. Great numbers of the fibers from the cingulum reach the entorhinal and subicular areas, which in turn project into the hippocampus.

Hippocampal system. The focal point of the hippocampal system is a curving strip of precisely aligned pyramidal cells

with dense apical dendrites projecting within the central core of the cornu Ammonis (Figure 3). Differences in size and other characteristics have prompted the division of the pyramidal cells into four fields designated, CA₁, CA₂, etc. The cells in CA₁ and CA₄ are the largest and send branches, the Schaffer collaterals, from their axons to end principally upon the apical dendrites of CA₁ and CA₂ pyramids (Figure 3). Other collaterals are given off by the pyramidal cells to end upon basket cells which produce recurrent inhibition of neighboring pyramidal cells, as discussed in Section 2.6.

There are three major efferent paths from cornu Ammonis: (1) a diffuse and poorly understood pathway into adjacent neocortex; (2) the hippocampal commissure or psalterium which connects the two hippocampi; (3) the fornix. The efferent hippocampal component of the fornix is formed by axons which gather on the hippocampal surface to form the alveus and then pass laterally and rostrally in the fimbria. The fimbrial fibers, augmented by contributions from the hippocampal gyrus, consolidate medially to form the fornix, which then descends into the septal area. The alveus, fimbria, and fornix are all in direct contact with cerebrospinal fluid since these structures form the ventromedial wall of the lateral ventricle. The projection into the septal area splits around the anterior commissure, forming the precommissural fornix, which terminates in the septal and preoptic areas, and the postcommissural fornix, which continues back through the hypothalamus to reach the mammillary bodies.

In man 2,700,000 fibers constitute the main body of the fornix and 900,000 fibers go into the hypothalamic portion. The corresponding figures for macaques are 500,000 and 100,000. The

FIGURE 2. Diagram of human brain showing components of the anterior commissure and stria terminalis. (Reprinted with permission of The Macmillan Company from Crosby, E. C., Humphrey, T., and Lauer, E. W. *Correlative Anatomy of the Nervous System*, p. 401. © The Macmillan Company, New York, 1962.)

fornix thus shows an over-all 5-fold increase in man and a 9-fold increase in its projection to the hypothalamus and medial mammillary nucleus. That these figures indicate an increase in the relative importance of the hippocampal system in man can be seen in other comparisons. The optic nerve, for instance, has about 1 million fibers in both man and macaque; and despite the much greater body and brain size in man there is only about a 2-fold increase (to about 1 million fibers) of the pyramidal tract in man versus macaque. The size of the neurons in man is smaller, yet the volume of the medial mammillary nucleus is about 6 times greater than in macaques, and it constitutes about 6 per cent of the total hypothalamic volume in man versus 3.5 per cent in macaques, further indicating the increased importance of the fornix-mammillary system in man.

There are, however, several complications in evaluating the relations in the fornix system. The postcommissural fornix gives off fibers into the hypothalamus, and it also receives hypothalamic fibers. In the rabbit the postcommissural fornix starts out with about 200,000 fibers, but only half reach the mammillary body; whereas in the cat with 160,000 fibers, 100,000 also reach the mammillary body. Midway in the hypothalamic portion of the fornix in the cat there are considerably fewer than 100,000 fibers, so that fibers must either branch as they approach the mammillary nuclei or new fibers join the fornix from the hypothalamus. In all species examined so far (rat, rabbit, cat, macaque) fornix fibers also pass beyond the mammillary body into the central gray. The pyramidal cells in CA₁ give rise to fibers which project principally to the anterior thalamic nuclei and to the mammillary body while those in CA₂ and CA₃ project mostly into the precommissural fornix and distribute to the medial and lateral septal nuclei, nucleus of the diagonal band and nucleus accumbens. However, not all of the fornix arises in the

hippocampus. In man and other species large bundles of fibers from area striata and the cingulate area pass directly through the corpus callosum and form the dorsal fornix. The destination of these fibers in the dorsal fornix is not well known, but they appear to terminate mostly in the hippocampus and septal area. Fibers (the white stria of Lancisi) from the induseum griseum, an embryological remnant of hippocampal tissue lying on the dorsal surface of the corpus callosum, also cut through the corpus callosum to join the dorsal fornix. In the rat and guinea pig some of the dorsal fornix projects directly to the superior central tegmental nucleus of Bektarev in the caudal mesencephalon.

In addition to these neocortical efferent fibers the fornix contains a large contingent of afferent fibers arising principally from the medial septal nucleus and nucleus of the diagonal band of Broca. It is thus possible that some of the proportional increase found in the human fornix system involves these afferent or neocortical efferent components in addition to the probable increase in efferents from cornu Ammonis. The relative increase in the medial mammillary nucleus, however, is definitive. In both the cat and rabbit there is an approximately one-to-one relation between the number of premammillary fornix fibers, number of cells in the medial mammillary nucleus, and number of fibers in the mammillothalamic tract. Many of the efferent fibers from the medial mammillary nucleus branch and project posteriorly into the deep tegmental nucleus of Gudden as well as into the mammillothalamic tract. The deep tegmental nucleus in turn projects upon the medial mammillary nucleus. The great majority of the fibers in the mammillothalamic tract are less than 1.5 μ . They form a dense plexus in the anterior thalamic nuclei, developing knotlike excrescences along their terminal filaments which are highly similar to the mossy fiber endings in the cerebellum.

The anterior thalamic nuclei, as mentioned above, project into the cingulate cortex. The latter projects into the hippocampal gyrus via the cingulum, and the path then returns upon the cornu Ammonis completing a potential loop of activity, the "Papez circuit": cornu Ammonis-fornix-mammillary body-anterior thalamic nuclei-cingulate gyrus-cingulum-entorhinal area-cornu Ammonis (Figure 4). Of course, several of the links in this "circuit" might be inhibitory rather than excitatory so that this arrangement is unlikely to be one for producing self-sustaining or avalanching activity. Furthermore, the topographic projections of the pathways are sufficiently complex that the resulting elaboration of impulses through the system would far exceed anything understandable in terms of a simple reentrant circuit.

The afferent pathways into cornu Ammonis are complex and still not fully defined. The afferents of the fornix terminate on the basilar dendrites and proximal portions of the apical dendrites of pyramidal cells in CA₂ and CA₄, and on granule cells in the dentate gyrus. The major afferent pathway arises in the entorhinal cortex (area 28), an area particularly well developed in man and higher primates. The principal afferent path into the entorhinal cortex in turn comes from the cingulum. A second well established system comes into the entorhinal area more diffusely from the olfactory tubercle and periamygdaloid cortex (uncus). This system undoubtedly serves as a relay for olfactory input but also conveys influences arising from many other sources. The inputs to cornu Ammonis thus filter through a continuous sheet of cortex the cytoarchitecture of which varies considerably as it approaches the hippocampal fissure and the dentate gyrus. Following this cortex from its rostral environs, all medial to the rhinal fissure and looping up the surface of the hippocampal gyrus, there can be identified: olfactory tubercle (anterior perforated space in man), prepiriform cortex, periamygdaloid cortex (piriform cortex, uncus in primates), entorhinal cortex, parasubiculum, presubiculum, subiculum, and prosubiculum. An interesting feature in several of these areas is the gathering of similar sized cells into clusters or islands. Most highly developed are the islands of Calleja in the olfactory tubercle (Figure 5). The giant cells in the islands of Calleja in man resemble motoneurons in appearance, but other larger islands are formed by granule cells only 5 μ in diameter. The afferent fibers to the islands of granule cells come from the direction of the caudate nucleus and form an extremely dense plexus within the island. Smaller clusterings of large or small cells are found in periamygdaloid and entorhinal cortex and in the subiculum. The periamygdaloid cortex of man also contains many cells with spectacularly developed basal dendrites. All these cortical areas have a pattern of organization which differs distinctly from that of the neocortex, and are classified as "allocortex."

The entorhinal area gives rise to groups of fibers which cut directly through the subiculum to end in complex ramifications among the dendrites of the granule cells of the dentate gyrus (Figure 3). This perforant or temporoammonic path also sends fibers among the apical dendrites of CA₁ and CA₂ pyramidal cells (Figure 3). The granule cells of the dentate gyrus send out very fine axons which, however, have large bulbous endings (Figure 5 in Section 2.6). These enclose the dendritic spines of the apical dendrites of CA₁ and CA₂ neurons. With the Golgi stain these bulbous endings give the axons a characteristic appearance so that they are called "mossy fibers" (Figure 3). The mossy fiber endings and/or the dendritic spines are peculiar in containing relatively large amounts of zinc.

Amygdaloid system. The amygdala is a group of a dozen or more nuclei covered by the periamygdaloid cortex of the uncus and forming part of the hippocampal gyrus (Figure 2). The nuclei can be divided into two groups: the corticomedial, which can be traced phylogenetically back to cyclostomes; and a

FIGURE 3. Schematic drawing of the structure and connections of cornu Ammonis. basolateral group which first appears in reptiles and in man forms the major component of the system.

Like those for the hippocampus, the connections of the amygdala follow two principal pathways: a diffuse one, which constitutes the predominant pathway in man; and a compact fiber bundle, the stria terminalis (Figures 1 and 2), which like the fornix follows a long, looping path into the septal-preoptic region and contains both afferent and efferent fibers. The description of these pathways is still garbled by the inability to separate the contribution of periamygdaloid cortex from that of the amygdala per se.

The stria terminalis arises mostly from the caudal portion of the corticomedial complex. It passes first caudally and then follows the upward and rostrally curving course of the tail of the caudate nucleus. As it plunges toward the anterior commissure, it divides into several components (Figure 2), a small part going rostral to the commissure, some fibers crossing through the commissure, but most descending into the medial preoptic area and anterior hypothalamus. In man and other mammals the stria terminalis is accompanied throughout its course by a bed nucleus, forming a strip of neurons which are

FIGURE 4. Summary of major connections of the hippocampal system.

clustered like the islands of Calleja. Similar islands occur in the central nucleus of the amygdala where the stria forms, and in nucleus accumbens and the substantia innominata of Reichert (Figure 5) not far from where it ends. At commissural levels the bed nucleus of stria terminalis enlarges considerably and becomes continuous with the bed nucleus of the anterior commissure and of the medial forebrain bundle (Figure 2); it has been described as a continuation of the anteromedial nucleus of the thalamus. It seems likely that the cells of the bed nucleus give rise to afferent fibers which course through stria terminalis into the amygdala. At commissural levels the cells in the bed nucleus of stria terminalis are innervated by many fibers which appear to be of thalamic origin. Some of these fibers continue on into the stria.

In man the stria terminalis is relatively small, and most fibers leaving and entering the amygdala course ventromedially through a sublenticular path. This bundle of fibers is about the size of the anterior commissure, although not nearly so compact. Within the amygdala it arises principally from the basolateral complex as the longitudinal association bundle of Johnston. It passes into the lateral preoptic area and lateral hypothalamus. Rostrally this ventral amygdalofugal pathway forms the diagonal band of Broca conveying fibers to the olfactory tubercle, substantia innominata, and medial septal nucleus.

The periamygdaloid cortex projects strongly into the amygdala, in part relaying olfactory input. The cortical nucleus of the amygdala receives fibers from the lateral olfactory tract and thus forms part of the same system as the periamygdaloid cortex. Afferents to the amygdala from other sources are ill defined. Two-way connections between the amygdala and insular-temporal cortex, however, have often been described.

The many nuclear groups seen in the amygdala with Nissl stains do not differ from one another in any obvious way in Golgi preparations, and nuclear boundaries are then obscured. Cells in the corticomедial group do seem to have fewer dendrites than do cells in the basolateral group. The system of axon collaterals in the amygdala is very profuse, indicating the occurrence of extensive intranuclear elaboration of amygdaloid activity.

Habenular-interpeduncular system. This system seems to be relatively undeveloped in man and has not been thoroughly studied in any species. The habenulae are nuclear masses of the epithalamus divisible even in cyclostomes into two distinctly different nuclei. An early problem in cerebral domi-

nance is presented in these structures since for petromyzonts the right habenula is always larger than the left while the reverse is true for sharks; and among teleostean species either right or left dominance or a symmetrical arrangement can be found.

In mammals the medial habenular nucleus consists of small, pale staining cells, 10 to 15 μ in diameter, of the "sensory" type (Section 2.5) with short dendrites which, together with afferent fibers from the stria medullaris (Figures 1 and 6), form very complex glomerular structures. The axons of these small cells pass directly into the medial aspect of the habenulopeduncular tract without branching. Cells of the lateral habenular nucleus, on the other hand, are of the typical "reticular" type, 20 to 26 μ in diameter. Fibers from the stria medullaris ramify profusely within the lateral nucleus. This diffuseness of effect is enhanced by numerous intranuclear collateral fibers given off by axons of the cells of this nucleus as they pass towards the habenulopeduncular tract. The lateral habenular nuclei are also interconnected with each other via the habenular commissure.

Fibers from the posterior septal area pass to the medial habenular nucleus, and the lateral habenular nucleus receives a powerful input from the preoptic area and the anterior nuclei of the thalamus (Figure 6). These inputs course in the stria medullaris. Many other sources for the stria medullaris have been claimed, but the foregoing probably constitute the major direct pathways. Electrophysiologically the fornix can be shown to project via the stria medullaris into the habenula and interpeduncular nucleus, but a synapse apparently occurs prior to the stria medullaris portion of this projection.

The interpeduncular nucleus contains cells of several types. The afferent fibers from the habenulopeduncular tract (Figure 1) lose their myelin upon entering the nucleus, and the bare axon then follows a peculiar "figure eight" course, crossing the midline and then returning to give off collaterals and break up into terminal arborizations. Afferents are also derived from the mammillary nuclei (Figures 1 and 6). Efferents project diffusely into the posterior tegmental area, particularly to the dorsal tegmental nucleus of Bekterev. These efferents join fibers of similar destination from the lateral habenular nuclei, which course down the habenulopeduncular tract but bypass the interpeduncular nucleus. A few fibers from the substantia innominata of Reichert in the preoptic area even follow the peculiar course through stria medullaris, habenulopeduncular tract, peduncular-tegmental tract to reach locus coeruleus!

The tegmental areas project back upon the interpeduncular nucleus and to some degree even to the lateral habenular nu-

cleus. They also project into the hypothalamus via the dorsal longitudinal fasciculus of Schütz as well as along the medial forebrain bundle system into the preoptic area, medial septal nucleus, and nucleus of the diagonal band of Broca. The latter two groups project into the hippocampus via the fornix (Figures 4 and 7).

Basal forebrain: Rhinencephalon. The entrance zone of the olfactory tracts on the rostrobasal surface of the brain is marked by extreme anatomical complexity. The system associated with the olfactory input is termed the "rhinencephalon" and, except for omission of neocortical components, the term rhinencephalon is essentially synonymous with limbic system. The realization that most rhinencephalic or limbic structures (with the possible exception of the dentate gyrus and the corticomedial components of the amygdala) are equally well developed in birds or cetaceans that lack olfactory input has prompted a

reappraisal of the role of the limbic system in olfaction. Nevertheless, it is clear phylogenetically that the limbic system has developed in association with the olfactory system. Furthermore, it is easy to understand how emotional reactivity and species-specific, stereotyped behaviors have been organized primarily under olfactory control. Every night for at least 100 million years the early vertebrates appraised their future solely with the olfactory sense as they swam forward in the dark and silent seas to eat or be eaten. The same nocturnal appraisal with all its associated reactions for mammalian prey and predator alike continues to provide a prime link to survival. Sexual contact and behavior have similarly come to be dominated by olfactory cues, and a well supported perfume industry bears familiar testimony to the lingering relevance of olfaction even in the sexual activity of man.

The primary olfactory input is processed first within the intricate systems of the olfactory bulb where a reduction of about 300:1 occurs between the number of incoming and outgoing fibers. Axons of the large mitral cells of the bulb pass centrally in the olfactory tract. They are joined by axons of cells from the anterior olfactory nucleus which are scattered within the tract. As the olfactory tract spreads into the brain, so too does the anterior olfactory nucleus, merging posteriorly with the prepiriform cortex and laterally into neocortex. The olfactory tract divides into lateral and medial components. The former spreads diffusely into prepiriform and piriform cortex, in the corticomедial nuclei of the amygdala, and, to some degree, into the lateral boundary of the anterior perforated substance. The smaller, medial olfactory tract of fine fibers, arising largely from tufted rather than mitral cells of the olfactory bulb, passes mostly across the anterior limb of the anterior commissure to the contralateral olfactory bulb. It probably also sends fibers into the medial septal nucleus, nucleus of the diagonal band, and the medial portion of the anterior perforated substance.

The latter area (Figures 1 and 5) is marked by a dense infiltration of small blood vessels and by the islands of Calleja. Its major afferent supply comes not from the olfactory tracts but from the septal area via the diagonal band. Its efferents form one of the major components of the median forebrain bundle and also project into the piriform and entorhinal cortex, medial septal nucleus, and olfactory bulb.

At its caudal border the anterior perforated substance joins part of the olfactory radiations of Zuckerkandl, which in turn merge with the diagonal band of Broca. The nucleus of the diagonal band is continuous with the medial septal nucleus and laterally with the globus pallidus, all being characterized by rather large cells of the reticular type. Further relation of the limbic system with a basal ganglia is found in this region with the continuation of the caudate nucleus as nucleus accumbens septi (Figure 5), and with the large cells of the substantia innominata of Reichert which are the rostral elements in a system known as the nucleus basalis of Meynert. The latter is associated with the globus pallidus and is particularly well developed in primates, forming clusters of cells between the optic tract and anterior commissure and the medioventral border of globus pallidus. The nucleus basalis degenerates following lesions of the temporal lobe.

As seen in several instances above and in phylogenetic development, the basal ganglia have an intimate relation with the limbic system. Furthermore, much stereotyped behavior depends upon the basal ganglia for its organization, and stimulation of the basal ganglia not uncommonly produces motivating effects. Thus there is some inclination to look upon the basal ganglia as important ancillary structures of the limbic system. However, since the basal ganglia are also intimately related with the neocortex, their equal association with the limbic system cannot be unduly emphasized.

The lateral septal nucleus is distinguished from the medial in having neurons of the "sensory" rather than the "reticular" type. Its afferents come predominantly from the fornix, and it is probable, because of its cell type, that it rather than the medial septal nucleus gives rise to the fibers that project to the sensory-type cells of the medial habenular nucleus (Figure 7). Stimulation of the septal area also evokes potentials in the dorsomedial nucleus of the thalamus.

The septal nuclei, nucleus of the diagonal band, the anterior perforated substance, and substantia innominata posteriorly shade over into the preoptic area, which in turn becomes the anterior hypothala-

mus (Figure 2). The preoptic area consists mostly of cells with short axons; receives input from the fornix, septum, and amygdala; and is traversed by and contributes to the medial forebrain bundle as well as fiber systems passing from piriform cortex to the dorsal medial nucleus of the thalamus. It also sends many fibers to the lateral habenular nucleus.

In summary (Figure 7), the basal forebrain is a point of focus and/or transit for about eight systems: (1) olfactory input to piriform cortex; (2) connections to and from the hippocampal system and the septal and preoptic areas; (3) connections to and from the amygdala and the preoptic-septal region; (4) connections to and from the tegmentum and septal area; (5) afferents to the habenular-interpeduncular system; (6) relations to the temporal lobes via the anterior commissure and the nucleus basalis; (7) afferents from piriform cortex to the magnocellular component of n. medialis dorsalis and the projection of the latter upon orbitofrontal cortex; and (8) efferents into the hypothalamus via the median forebrain bundle. In addition, recent electrophysiological evidence indicates that this basal forebrain region distributes centrencephalic influences onto the dorsal convexity of the frontal lobe.

Neuroendocrinology and the Hypothalamus

Anatomy. The connections to and from the hypothalamus place it definitively within the limbic system, and the physiological and behavioral correlates of its activity affirm this classification. In Golgi stain the cells of the hypothalamus are all of the reticular type, and in the lateral hypothalamus particularly, the reticular organization is also apparent in the arrangement of fibers and cells. Of course there are many varieties of "reticular" neurons, and in man Nissl stains demonstrate about nine principal cell types in the 17 nuclei into which the hypothalamus can be divided. For the present discussion, however, only the anterior, lateral, and ventromedial hypothalamic areas need be considered plus the nuclei specifically giving rise to neurosecretory tracts.

The ventromedial nucleus seems to be organized to serve as a distribution center. Fibers from this nucleus first ramify extensively within it, then pass to all parts of the hypothalamus, especially to anterior and lateral areas, some attaining the lateral area of the other side via Meynert's commissure associated with the optic chiasm. The afferents to the ventromedial nucleus are mostly of small calibre and branch profusely, thus producing a diffuse and random appearing network. The terminals are small but filled with the usual type of synaptic vesicles. The afferent and efferent exchange of the lateral hypothalamus is with distant areas, i.e., outside the lateral hypothalamus. It probably receives more nonhypothalamic afferents than any of the other hypothalamic areas. Collaterals of efferent fibers from the lateral hypothalamus do not ramify within this area but instead project into the medial nuclei.

The most powerful afferent system playing upon the hypothalamus arises in the rostral mesencephalon, i.e., in the reticular formation and central gray. There are essentially no direct connections of neocortex with the hypothalamus, but since the dorsal prefrontal cortex projects into the foregoing

mesencephalic areas, a potentially strong link exists. The amygdala and especially the septal-preoptic area also contribute numerous afferents to the hypothalamus.

Descending efferents from the hypothalamus pass through the dorsal longitudinal fasciculus of Schütz, but they are rather meagre from the medial nuclear groups. This suggests that most of the longer efferents arise in the lateral hypothalamus, although this possibility is difficult to study independently of the medial forebrain bundle. It does indicate that the dorsal longitudinal fasciculus is predominantly afferent to the hypothalamus. None of the hypothalamic efferents reach the spinal cord, and most terminate in the midbrain rather than medulla. The rostromedial groups project anterodorsally and contribute fibers to the stria medullaris and possibly stria terminalis.

Two efferent paths supply neurosecretory material to the hypophysis. The first is the well known hypothalamohypophyseal tract, in man about 100,000 fibers, arising from large cells in the supraoptic and paraventricular nuclei and terminating upon blood vessels (Figure 8) in the neurohypophysis (posterior lobe of the pituitary gland). The supraoptic and paraventricular nuclei have a particularly rich blood supply. Within the cell bodies and all along the nerve fibers aggregations of specially staining material are readily discernible. The fibers often have a beaded appearance from the presence of organized masses (Herring bodies) of this material ranging in size up to that of the cell body itself. For many years it was thought that the pituicytes within the neurohypophysis stored the hormonal material. Electron microscopic evidence (Figure 8), however, indicates that the 750- to 2000-Å neurosecretory granules of the nerve endings only rarely get into the pituicytes (seemingly by phagocytosis). The pituicytes are similar in appearance to fibrous astrocytes. In the newborn monkey they form a glia-like barrier which disappears from around the blood vessels as the animal matures. Their role, if any, in the hormonal activity of the posterior lobe is thus unknown. Perhaps equally puzzling in the neurosecretory process is the presence of typical synaptic vesicles along with the secretory granules and small Herring bodies in the endings which the hypothalamohypophyseal tract forms upon the capillary network within the posterior lobe (Figure 8). In macaques the hormonal release appears to be accomplished primarily by the passage of intact small Herring bodies into the vascular system. Nerve endings are also sometimes pinched off and pass into the blood stream. In addition, the secretory granules of the nerve endings are depleted individually of their osmophilic core, as in the opossum (Figure 8), and/or release the entire neurosecretory granule.

The other secretory efferent path is the tuberoinfundibular tract. This is a fine-fibered system arising from small cells of the periventricular, tuberal, and possibly other nuclei. The beads of secretory material found in these fibers have entirely different staining characteristics from those in the hypothalamohypophyseal tract. The fibers terminate upon capillaries and as palisades overlying the "Mantelplexus," a dense capillary plexus on the surface of the pars tuberalis.

The neurosecretory material could be carried thence to the adenohypophysis by way of the portal circulation. However, beyond the fact that the hypothalamus definitely controls the adenohypophysis and that the portal circulation moves from the tuberal region to the pars distalis (anterior lobe), morphological knowledge concerning the transport, storage, and release of the hormonal materials is almost nonexistent.

Neurohypophyseal system. Two types of response are produced by neurohypophyseal hormones: (1) alteration of the permeability of certain membranes to water; and (2) contraction of smooth muscle. Two different hormones are secreted, but each can to some

degree produce both types of responses. The hormones are peptides that are species-specific and display a fascinating phyletic constancy (Figure 9). Oxytocin is present from amphibia on through mammals. In the latter it is particularly effective in producing uterine contractions and milk ejection. Arginine vasopressin is found in monotremes, marsupials, and most mammals. It causes contraction of arteriolar smooth muscle and thus increases blood pressure. Its major role, however, is the control of the osmolality of the blood by its action upon water reabsorption in the distal tubules of the kidney. In this latter role it is called the "antidiuretic hormone" (ADH). Its absence following hypothalamic lesions has long been recognized as the cause of diabetes insipidus.

Conditions which change the osmolality of the blood quickly affect the release of ADH and alter the amount of neurosecretory material which can be demonstrated in the hypothalamohypophyseal system. Thus, drinking hypertonic solutions or injecting them intravenously causes a great outpouring of ADH to conserve water, and the neurosecretory material then becomes sparse. On the other hand, overloading the organism with water induces a spectacular increase in the amount of neurosecretory material. The stainable material seen with the light microscope is not the hormone *per se* but is likely to be a lipoprotein to which the hormone is attached. The role of this protein material or even whether the hormone is indeed attached to it in the nerve fibers remains uncertain.

ADH secretion is also altered by many seemingly nonspecific factors such as pain, cold, or electrical stimulation of certain limbic areas. The neural control is thus rather complex, and the question arises whether or not it is integrated primarily within the supraoptic nuclei and whether secretory cells have the electrophysiological behavior of other neurons. The latter question received an unequivocal answer in the goldfish where intracellular recordings can be made from secretory neurons in the preoptic nucleus (which in reptiles, birds, and mammals differentiates into the supraoptic and paraventricular nuclei). Spike potentials, excitatory and inhibitory postsynaptic potentials, etc. are all comparable to those of any large neuron. Antidromic stimulation of the preoptohypophyseal tract induces inhibitory postsynaptic potentials of such short latency as to suggest that recurrent collaterals of the secretory neurons have direct intranuclear inhibitory connections. Extracellular records from neurons in the mammalian supraoptic nucleus also demonstrate spike potentials, and their background frequency is determined by the osmolality of the blood. Since a hypothalamic island containing the supraoptic nuclei and intact hypophyseal system isolated from the rest of the brain can still respond to changes in blood electrolytes, it seems very likely that the secretory neurons are themselves the osmoreceptors. Their possession of normal electrophysiological activity also suggests that these neurons might integrate activity impinging upon them from several other neural sources, and that it is neural discharge which liberates the hormone from the nerve endings. Support for the latter concept comes from the fact that neurohypophyseal hormonal stores, though temporarily ample, cannot be released by hypertonic injections following section of the hypothalamohypophyseal tract.

Adenohypophyseal system. Six hormones are known to be secreted by the anterior lobe of the pituitary gland. These hormones are peptide or protein in nature and have varying degrees of specificity. They control the action of other endocrine glands. Adrenocorticotrophic hormone (ACTH) is the only one so far identified chemically. It is a straight pep-

FIGURE 8. Diagram of the electron microscopic features, at about 9000 \times , of the neurohypophysis of the opossum. *c*, lumen of blood vessel; *e*, endothelial lining of capillary with numerous "pores"; *s*, septal zone which consists of collagen bounded by basement membranes (*b*). The septal zone separates the axon terminals (*t*) from the blood vessel wall, and contains mast cells (*m*) and fibroblasts (*f*). Synaptic vesicles (*arrow*) are clustered almost exclusively at tips of terminals abutting on the septal zone. The axons themselves (*a*) are generally free of neurosecretory granules (the dark, small spherules with light ring about them). In some axon terminals (*X*) many of the granules have lost their osmiophilic core. The small Herring body (*H*) also contains neurosecretory granules. The pituicytes (*p*) are relatively clear, with a light nucleus (*n*) and occasional dense inclusions (*double arrow*). The arrangement in macaques is basically similar to this except for presence of greater numbers of small Herring bodies and a reduced pituicyte system. (From Bodian, D. Cytological aspects of neurosecretion in opossum neurohypophysis. *Bull. Johns Hopkins Hosp.*, 113: 57, 1963.)

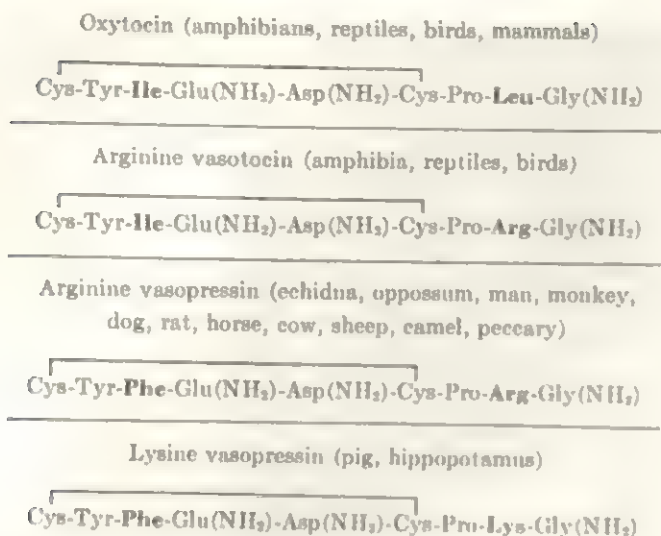

FIGURE 9. Chemical structure of neurohypophyseal hormones in various species.

tide of 39 amino acids having a molecular weight of about 4,500. The secretions of the adrenal cortex, which regulate salt and sugar metabolism, leukocyte behavior, and general body responses to inflammation or "stress," are controlled almost completely by ACTH. The other hormones are: follicle-stimulating hormone (FSH) and luteinizing hormone (LH), necessary for maintenance of functioning gonads in either sex and paramount in the regulation of the female sexual cycle; prolactin, which produces secretion from the mammary glands and also has a luteotropic hormone (LTH) effect; thyroid-stimulating hormone (TSH), controlling general metabolic rate and thus a wide variety of body functions and neural maturation; somatotrophic hormone (STH), which also regulates body metabolism in a general and poorly understood manner and controls growth, particularly by its influence on bone epiphyses.

There are only two cell types, the acidophils and basophils, in the adenohypophysis which are likely to be the source of these six hormones. Which hormone comes from which cell is by no means certain. Furthermore, hormonal production is almost wholly dependent upon the hypothalamus. The one exception to this is prolactin, the production of which is inhibited by the hypothalamus, so that following hypothalamic lesions, transplantation of the gland beyond reach of the portal circulation, or explantation of the gland to artificial media, prolactin production is augmented while the other hormones essentially disappear. Adding hypothalamic but not other neural tissue to a culture of the adenohypophysis supports the production of ACTH. Similarly, if adenohypophyseal tissue is implanted into the hypothalamic area from which the tuberoinfundibular tract arises, normal basophils and sexual cycles in hypophysectomized female rats can be maintained, but if the tissue is implanted elsewhere in the brain the basophils atrophy and the females remain anestrus. The survival of acidophils in such transplants depends solely upon whether the thyroid gland is maintained in a good trophic condition.

The evidence thus points strongly to the likelihood that the tuberoinfundibular tract releases substances into the portal circulation which are necessary for the manufacture and release of the adenohypophyseal hormones. Whether these substances, which seem to be peptides, are incorporated into the hormones themselves or merely exert a control over the secretory cells remains unknown, and they are presently spoken of only as "releasing factors."

In a number of instances release of adenohypophyseal hormones has been obtained by electrical stimulation of the hypothalamus or other areas of the limbic system, whereas stimulation of the adenohypophysis itself is ineffective. More important, of course, is the fact that a great variety of natural stimuli processed via the nervous system are capable of profoundly influencing hormonally controlled processes. Most familiar perhaps is the production of menstrual irregularities in women by emotional disturbances. The influence may be more subtle, as the frequent failure of pregnancy to develop in mice under conditions of crowding or when exposed to the odor of male mice of another strain. In many species the sexual cycle is under control of photoperiodicity. Ovulation occurs in some species (e.g., cat and rabbit), only following vaginal stimulation, and such stimulation can be demonstrated to produce bizarre electrical patterns in the lateral hypothalamus. Pain or other "stress" causes great augmentation of ACTH release. The neural mediation of these effects was dramatically demonstrated in a dog maintained for months with its brain stem transected at the collicular level. ACTH was not released in this animal following a laparotomy, which is usually a powerful stimulus, whereas it was augmented when the animal was restrained in a strange environment—thus incidentally demonstrating some degree of "awareness" in the isolated forebrain.

The neurons from which the tuberoinfundibular tract originates also seem to be sensitive to the titer of hormones secreted by the target organs of the adenohypophysis. This chemoreceptor function of the hypothalamic neurons thus provides for feedback regulation of the hormonal system. A high hormone titer will cause the hypothalamic neurons to diminish production or release of the appropriate "releasing factor" and thus lower stimulation of the target organ by the adenohypophysis. If the receptive mechanism of the hypothalamus is "deceived" by the implantation of a pellet of hormone, such as estradiol, testosterone, or hydrocortisone, in the appropriate nucleus, the curtailment of "releasing factor" and consequent

failure of adeno-hypophyseal support of the target organ is so severe as to be equal to hypophysectomy in its effects.

Other possible neurohormonal systems. After thyroidectomy, cells in the medial habenular nucleus undergo a 10 to 20 per cent decrease in size. Habenular lesions, on the other hand, produce a slight obesity, detectable changes in the histology of the adeno-hypophysis and thyroid, and an impaired ability to increase thyroid activity upon exposure to cold. This somewhat tenuous connection of the habenula with the thyroid gland can be associated with an equally suggestive but tenuous relation to temperature regulation. The major source of habenular afferents is the preoptic area, which is directly and exquisitely sensitive to temperature changes. Local heating of the preoptic area inhibits shivering and produces panting without reference to general body temperature. The effect can be imitated by electrical stimulation either in the preoptic area, in the habenula, or in the interpeduncular nucleus. Section of the stria medullaris, however, does not abolish panting to raised body temperature (whereas preoptic lesions do), but it does forestall the pronounced "emotional" panting seen in rabbits upon restraint.

A role for the habenula in temperature regulation might have arisen phylogenetically from its association with the pineal organ. The latter has two distinct components, one for photoreception, the other for secretion.

In fish, amphibia, and reptiles both elements are present. In some the pineal eye is very well developed with a clear cornea, typical rods and cones, and ganglion cells from which spike potentials can be recorded in response to light. Behaviorally, the pineal eye seems to effect changes in pigment distribution and temperature regulation (basking in the sun) and have some influence over thyroid function. In primitive vertebrates the glandular portion of the pineal organ appears to be even more important than the hypophysis, and it is only this glandular element which survives in mammals. The pineal gland receives a rather rich innervation from fibers arising in the superior cervical ganglion. They end upon pineal parenchymal cells in terminals packed with the norepinephrine type of synaptic vesicles.

The nature of the undoubted secretion of the mammalian pineal organ remains elusive as does its relation with the subcommissural organ with which it is connected by a portal circulation reminiscent of that between the hypothalamus and hypophysis. The circulation passes from the subcommissural organ to the pineal body, but the analogy cannot be pressed far since the subcommissural organ is composed of secretory cells closely similar to those in the pineal body. The subcommissural organ lies just beneath the habenular commissure and covers the surface of the posterior commissure and the oral-dorsal surface of the aqueduct. It is richly vascular, with rosettes of secretory cells surrounded by capillaries. In addition to secretion into the blood stream, it also gives rise to a strange secretion into the cerebrospinal fluid. This is Reiser's fiber, a continuous strand of protein, 5 to 25 μ in diameter in man, which passes through the aqueduct into the fourth ventricle and often down the central canal of the spinal cord. In lower forms it reaches the end of the central canal, and the secretion leaves via a network of periepithelial lymphatic vessels. The subcommissural organ is particularly well developed in young individuals and regresses considerably in

most adults. The organ is apparently concerned with water and electrolyte metabolism and is related to the aldosterone secretion of the adrenal cortex. In this connection it is of interest that adrenalectomy also produces an increase in size of cells in the medial habenular nucleus.

The subformical organ, lying against the fornix at the rostral end of the third ventricle and adjoining the origin of the choroid plexus, is a nodule of tissue highly similar to that of the pineal-subcommissural system. Its function is completely unknown save for its serving as a receptor site for the production of hyperglycemia following the intraventricular injection of morphine!

Behavioral Aspects

Electrical stimulation of the limbic system in anesthetized animals readily reveals its links with the autonomic and endocrine systems. Cardiovascular and/or respiratory responses are common, as are changes in muscular tone; and a wide variety of other effects is obtained, among them ovulation, gastric or bladder motility, penile erection, chewing, licking, swallowing, salivation, piloerection, vocalization of attack, and changes in blood sugar or renal function. Lesions in the limbic system similarly affect various aspects of these functions. It is, however, in the behavior of waking, active animals that the most significant effects are obtained. Interest in the behavioral manifestations of limbic system disturbances received a great impetus in 1937 with the discovery, made on a monkey prophetically named "Aurora," of the constellation of effects now known as the Klüver-Bucy syndrome following bilateral removal of the tips of the temporal lobes. The four major effects are: (1) tameness and lack of fear; e.g., the wild animal no longer flees from man or snakes; (2) hypersexuality; (3) persistent oral exploration (objects repeatedly mouthed and grasped with lips in preference to hands; dietary changes also notable); and (4) visual agnosia (objects compulsively explored again and again, difficult visual discriminations require very extensive training even though learned preoperatively). It is conceivable that this peculiar visual deficit accounts in some measure for symptom (1) above.

The lesion producing this syndrome includes all of the uncus and amygdala, and most of the hippocampus. If the lesion is limited to neocortex, there is a permanent deficit in visual abilities (and the optic radiation is intact), and temporary tameness and oral exploratory behavior.

Fear-aggression. Electrical stimulation throughout an extensive subcortical area in freely moving cats produces growling, spitting, pupillary dilatation, piloerection, and arching of the back. Whether the animal flees or attacks under these circumstances is determined as much by its opportunities as by the location and intensity of the stimulation. Frequently it endeavors to escape from the locale where it found itself upon onset of the stimulation, but if escape is blocked, or there is a suitable object such as a rat, another cat, a stuffed animal, or an experimenter's

hand in the immediate vicinity, a directed attack is made upon this object. Cats so stimulated will learn to seek objects to attack, as though in such circumstances the performance of the attack was rewarding.

Stimulation in the amygdala, afferent fibers in stria terminalis, preoptic area, much of the dorsomedial hypothalamus and especially the central gray produces these effects. Lesions in the hypothalamus do not interfere with the effects obtained by stimulation of the central gray, whereas destruction of the central gray temporarily abolishes such responses to stimulation at other loci and subsequently predisposes the animal to flight rather than attack. Stimulation at slightly more lateral loci in the hypothalamus can produce attack which has more the aspects of hunting-predatory behavior, without such severe spitting, crying, and piloerection. Elements of this hunting behavior can be "released" by large lesions involving the central gray and dorsal tegmentum. Cats with these lesions may spend their entire waking life slinking upon nonexistent prey, carrying objects in their mouths as though they were prey, or fishing and pawing into holes, corners, or water. In other words, they constantly display portions of predatory behavior completely out of context.

Some rats immediately kill and eat mice placed in their cage while other rats will never harm the mice. This is a genetically determined trait. However, "non-killers" can be converted into savage killers by bilateral removal of the olfactory bulb, or prepiriform cortex, or section of the lateral olfactory tract. It might be inferred from this that killers merely have a deficiency in their olfactory system. This is disproven, however, by the fact that killers will start to attack a young rat the size of a mouse but abruptly stop upon smelling it. Although handicapped in sensing the presence of a mouse, rats without olfactory bulbs with their eyes closed, whiskers cut, and ears filled with wax will still kill immediately upon contacting a mouse, or in this instance a small rat as well. The killing is separable from eating since animals that are aphagic and adipsic following lesions of the lateral hypothalamus will still kill mice even though they don't eat them. Bilateral destruction of the central (not lateral nor basal) nucleus of the amygdala or complete interruption of the diffuse subpallidal amygdalohypothalamic path permanently abolishes the killing behavior. Section of stria terminalis has no effect. It is thus possible to specify with considerable precision the anatomical substrate organizing this aggressive behavior.

Feeding. Electrical stimulation of the lateral hypothalamus just within the debouchment of ansa lenticularis causes fully satiated animals to eat avidly. Bilateral lesions in this area produce aphagia and adipsia. With long and careful nursing some degree of natural feeding can be restored, but usually only for the most palatable foods, and adipsia is likely to be permanent. The deficit is one of appetite rather than

ability to feed. Adipsia together with impairment of temperature regulation but without aphagia is produced by preoptic lesions. Lesions in the ventromedial nucleus of the hypothalamus, on the other hand, produce animals that are savage and obese. Their obesity, however, is maintained only with palatable food, and they will starve more readily than normal animals if forced to feed exclusively on unpalatable material such as food with quinine in it.

As a first approximation it can be hypothesized that the lateral hypothalamic area is concerned with appetitive food intake and that the ventromedial nucleus acts as a "satiety center," inhibiting the lateral-lying "feeding center." The concept gains some support from the rather strange fact that adrenergic agents placed in the lateral hypothalamus induce feeding behavior whereas cholinergic agents at the same locus or in many other loci in the limbic system induce drinking of water. A number of facts, however, point to the possibility that the globus pallidus may participate in the organization of feeding behavior. The sites of electrical stimulation in the lateral hypothalamus from which feeding can be induced lie directly in the path of pallidofugal fibers, and stimulation along their course in the ventral tegmental area of Tsai and beneath the central gray is also able to elicit immediate feeding in satiated animals. Cholinergic drugs in the globus pallidus also elicit feeding, and lesions there produce aphagia. Finally, cats with cortex and basal ganglia removed do not feed spontaneously, even though the lateral hypothalamus has not been directly affected, whereas essentially normal feeding behavior is present in decorticate cats with most of the basal ganglia intact.

Sex. Since sexual activity in most laboratory animals except primates is under rather close hormonal control, efforts to elicit sexual behavior by electrical stimulation of the brain have not been numerous. Such stimulation in squirrel monkeys has revealed several areas in the limbic system from which penile or clitoral erection can be induced. In this species, however, penile erection serves as a display in social interchange within the colony so that the sexual significance of the systems studied is contaminated by other complex behaviors.

The hypersexuality of the Klüver-Bucy syndrome has been well studied in cats, and the relevant locus has been found to lie in the piriform cortex. Male cats with lesions in this area attempt copulation almost continuously in any territory and with any object they can grasp. Without testosterone such behavior gradually subsides. The complex sexual pattern of "calling," treading, and rolling seen in the female cat is also entirely under control of the estrogen titer of the blood. It can, however, be elicited in full by implantation of a small pellet of stilbestrol in the posterior hypothalamus, which does nothing to the peripheral genital system.

The situation has been observed in an even more

fascinating manner in rats. Implantation of testosterone in the medial preoptic area of either male or female rats can occasionally elicit strong maternal behavior of nest building and retrieval of pups. The demonstration that males possess the neural organization necessary for maternal behavior is of considerable import. On the other hand, when the testosterone is placed in the lateral, preoptic area, male sexual behavior of mounting and thrusting is sometimes displayed by female rats.

Rats seem to be born with a sexually undifferentiated nervous system of the female pattern, which then normally either becomes fixed by the presence of estrogens or changed into the male pattern by testosterone. The permanence of the fixation of these behavior patterns by the early hormonal environment is remarkable. A single injection of testosterone in a 4-day-old female produces an adult that has no cycles. The trouble is in the brain, not the ovary or adenohipophysis, for either of the latter appropriately transplanted into an ovariectomized or hypophysectomized female, previously normal, can then support normal sexual function, i.e., when controlled by a sexually competent hypothalamus. So far such effects have not been obtained in rabbits, a species that, unlike the rat, is normally acyclic.

Self-stimulation. By training an animal to press a lever to obtain food and then arranging things so that each lever press also delivers stimuli to particular loci in the brain it is possible to determine whether the animal seeks, avoids, or is indifferent to stimulation in various neural systems. From such studies it is immediately apparent that the overwhelming majority of points where stimulation is either sought or avoided lie within the limbic system. This is perhaps not surprising in view of the goal-directed activities organized by the limbic system, but it does stand in striking contrast to the fact that, except for occasional and short-lived curiosity, animals are almost wholly indifferent to neocortical or cerebellar stimuli, even those producing violent movements.

The motivational effects produced by central stimulation are often stronger than those produced by natural stimuli. For instance, rats given an opportunity to choose between stimulating the medial forebrain bundle in their lateral hypothalamus and eating will, even though starving, choose the hypothalamic stimulus. This becomes somewhat paradoxical when a point is selected in the lateral hypothalamus where stimulation induces the animal to eat. It might be supposed that the rat applies stimuli which make it hungry rather than eating the food to satisfy that hunger. However, the tests have not been that definitive since the stimulation which demonstrates that the rat will eat when stimulated endures for several seconds, whereas that stimulation which the animal chooses to apply to its brain lasts only 0.5 second. The choice of central stimulation over food nevertheless remains mysterious. Since the limbic system is particularly susceptible to seizure

activity, and seizures have an amnesic effect, it is possible that the self-stimulation arises from a confusional state; e.g., the animal initiates a lever press, but the resulting stimulation erases the record or feedback from the action and the animal is left where it was—about to press the lever, etc. This supposition gains support from the fact that much higher currents are required at many loci for the initiation and maintenance of self-stimulation than for the animal to perceive and utilize stimulation of the same neural point as a signal. In addition, self-stimulation often produces bizarre electrical activity in the limbic system.

However, while confusional states and seizure activity may be associated with self-stimulation in a number of instances, it is very unlikely that self-stimulation at most loci arises from such factors. Throughout the medial forebrain bundle system, which yields the highest rates of self-stimulation, the currents required for the effect are very low. It can also be shown that the animals are in contact with and perceiving events in their environment at all times during most self-stimulation. Finally, administration of anticonvulsant drugs has the paradoxical effect of increasing self-stimulation, to some extent by curtailing seizures which were an interfering side effect.

Exploratory experiments indicate various interactions between androgen level or hunger, avidity for self-stimulation, and location of stimulating electrodes. A further complication is found with variation of the duration of the burst of stimuli resulting from each lever press. The effects of train-duration are particularly dramatic for stimulation of the posterior hypothalamus in cats. For a 0.5-second train the animal presses every 2 to 3 seconds for 10 to 20 minutes at a time, each press giving pupillary dilation, a slight dart forward, and piloerection. The animal appears as though it is frightened, but presses avidly. If, however, the stimulus lasts for 1.0 rather than 0.5 second for each press, the stimulation becomes strongly aversive.

Experiments so far suggest that from any particular locus the excitation can be elaborated over several different pathways. Ventral tegmental lesions, however, may abolish self-stimulation in septal loci. This is of considerable interest since stimulation of these tegmental sites is extremely aversive. It is possible that one of the effects of self-stimulation is to dampen the activity of aversive systems. This rather hazy concept does receive some support from work with human subjects. A few patients have apparently found that stimulation in septal areas relieves "anger and frustration." There seems little question but that such stimulation might have important therapeutic value were only enough of its neurophysiology understood. On the other hand, the conscious concomitants of self-stimulation in man are often so vague or bizarre as to discourage much hope of being

able to comprehend the psychological effects on man or animals in any simple terms. Some of the effects are frankly sexual, but a "cool taste," a "high" feeling, or a feeling of being about to remember something interesting are the best verbal reports of these effects which some self-stimulating patients can give. Points presumed to be in the central gray or hippocampus yield reports of melancholy, terror, or "sick all over." Such adverse effects sometimes survive for considerable periods but can be promptly relieved by stimulation at loci which yield self-stimulation. Such drastic changes of mood affirm the import of activity of the limbic system. Reliably specific therapeutic control of these powerful effects by means of localized stimulation will require a great extension of present knowledge and techniques, but few areas of research hold greater promise than this for relief of human suffering.

Memory. The temporal lobe has some special relation to memory processes, particularly those concerned with the recording of recent events. Just which temporal lobe structures are associated with these phenomena is still uncertain, but most evidence points to the hippocampus. If more than the uncus and amygdala are included, bilateral loss of the inferior temporal area in man makes the learning or long term retention of new information almost impossible. Basic intelligence and skills and memories acquired earlier are essentially unimpaired in such individuals, yet they ask the same question again and again, remembering neither the answer nor the fact that they have previously asked. Old friends and names are recognized, but new are not. Such patients find their way about formerly familiar neighborhoods but are unable to acquire such orientation in new situations. They can describe in detail plays in baseball games attended in the remote past before their injury but can recall virtually nothing of a game witnessed just a few minutes prior to questioning.

Electrical stimulation within the depths of the temporal lobe in epileptic patients can produce an amnesia for recent events, without apparent disturbance for recall of events long past. The more prolonged the stimulation, the longer the duration of amnesia and the farther back in time the patient's memory may be disrupted. Thus in one patient stimulation for 2 seconds disturbed recall of a five-digit number given just before the stimulation, with recovery occurring within 1 to 2 minutes. Stimulation for 5 seconds produced amnesia for events of the current day, e.g., what had been eaten for breakfast, and recovery required 5 to 10 minutes. With stimulation for 10 seconds the patient usually could no longer remember coming to the hospital 3 weeks earlier, why he was there, who the doctor was, etc.; yet could describe boyhood friends and experiences. Such a state required 1 to 2 hours to clear. On the

other hand, stimulation of the more dorsal portions of the surface of the temporal lobe in other epileptic patients is able to evoke a vivid reliving of past events. Such experiences are sometimes reproducible upon repeated stimulation and often involve auditory, visual, and emotional components in a fully integrated hallucination of a previous experience.

Lack of understanding of the nature of the deficit apparent in short term memory, produced in man by temporal lobe lesions, together with the great complexity of these effects, makes it difficult to devise tests for demonstrating comparable defects in animals. Macaques with temporal lobe lesions and displaying the typical Klüver-Bucy syndrome are best characterized as having an inability to learn complex auditory and visual discriminations rather than as lacking short term memory. Some of the deficiencies in human patients can be similarly described, i.e., as a deficit in learning rather than retention per se.

Cats are unable to perform a simple leg flexion conditioned reflex during the course of bilateral seizures in the hippocampal complex. Yet if all the animal's training, i.e., pairing of conditional and unconditional stimuli, is given only during the presence of these seizures, it can be shown that learning still occurs. Following such training, flexion conditioned reflexes will be given immediately to the conditional stimulus if it is presented while the cat is in the normal state, i.e., without seizure activity in the limbic system. Thus, abnormalities of hippocampal activity would appear to interfere with performance but not with learning. A similar conclusion can perhaps be drawn from studies in which the electrical activity of the hippocampus of cats was monitored during the learning and performance of a visual discrimination. When correct discrimination was made, it was accompanied by a highly regularized theta rhythm at 6 per second. Subthalamic lesions produced a temporary disturbance in this rhythm, and, as long as it was disturbed, the animals failed to discriminate properly although the learned motor act of selection and approach was performed normally. Thus, in this instance, a less overwhelming interference with hippocampal activity is manifested in a more subtle loss in performance.

It is apparent from the foregoing and many facts not discussed here that in addition to its role in instinctual behavior, motivation, and the control of autonomic-endocrine effects the limbic system has an important, although ill defined, role in learned behavior and memory.

Clinical implications. It can readily be appreciated that abnormalities in the function of the limbic system can produce gastric ulcers, pulmonary edema, or menstrual irregularities. Not so easily perceived, perhaps, is the concept that pathological activity in the limbic system is capable of producing psychosis and may be responsible for many, if not all, psy-

chotic states. The major evidence for this comes from two sources, psychomotor epilepsy and the psychotropic drugs.

The features of temporal lobe epilepsy are extremely varied. The "uncinate fit" is usually ushered in by an aura of unpleasant odor, epigastric sensation, and a feeling of fear, strangeness, or familiarity (*déjà vu*). The fit may involve only a transient clouding of consciousness and a series of automatic movements such as chewing, although in many instances a full convulsive seizure also develops. Of interest to psychiatry is the fact that this "psychomotor" epilepsy displays other forms which range from episodic assaultive rage to frank schizophrenia. In developing the thesis that psychopathology may be predominantly associated with disturbances in the limbic system, a number of difficulties arise. First is the indisputable fact that a few patients with psychomotor epilepsy, electroencephalographic spiking in the temporal area, or demonstrated small lesions in cornu Ammonis retain a normal personality. However, such findings can plausibly be attributed to unilateral or small lesions, or to locations or processes which differ from those producing personality disturbances. The more striking fact is that from 50 to 90 per cent of patients with psychomotor epilepsy or temporal lobe spiking manifest psychopathology which may be identical with that seen in the psychoses that are not accompanied by demonstrable brain lesions. The psychiatric problem is associated with the temporal lobe rather than with epilepsy per se since most authorities agree that focal epilepsy in other areas seldom produces personality changes.

Since the disturbance in personality is more or less permanent, it cannot be attributed wholly to the temporal lobe episodic seizure. It must be presumed instead that epileptogenic foci in the temporal lobe produce a continuing abnormal neuronal discharge just as occurs from such foci in dorsal neocortex, and that this background abnormality results in the alteration of personality. On the other hand, it can also be recognized that in some instances psychomotor seizures may last for minutes or even hours and that patients at such times can still perform complex acts, such as driving a car, for which they are subsequently wholly amnesic.

Patients with psychomotor epilepsy are not uncommonly diagnosed as having schizophrenia. The question arises, of course, as to whether they have one disease or two; i.e., schizophrenics might have psychomotor epilepsy in addition to schizophrenia. A distinction is made on the fact that such patients with psychomotor epilepsy obviously have a motor component in their seizures and also have more frequent and prolonged remissions than do schizophrenics. However, since patients with the diagnosis "psychomotor epilepsy" can be every bit as paranoid and psychologically disturbed as those whose diagnosis is

"schizophrenia," the most parsimonious approach would be to consider these but slightly different manifestations of a basically similar pathology. Procedures which control the epilepsy usually do not relieve the psychosis, but they often instead have the paradoxical effect of exacerbating it. (But, convulsions are used as therapy for psychoses.) On the other hand, a few dramatic instances are also known in which unilateral temporal lobectomy has relieved profound psychoses that were associated with electrical and histological abnormalities of cornu Ammonis. Thus, as a general rule, procedures which affect the epilepsy also influence the psychosis in a manner at least compatible with the hypothesis that there is a single etiology for the two conditions.

The other side of this coin is that electrical abnormalities would undoubtedly be a much more common finding in psychotic patients were they all studied with intracerebral electrodes. High voltage, convulsive spikes generated by applying strychnine to the mesial temporal cortex in man simply give no indication of their existence when records are taken only from the scalp.

Similarly, in Figure 10 no indication of the underlying pathology can be seen in records from the scalp until the patient is in a definite psychomotor seizure (Figure 10D). This patient displayed basic schizoid trends with paranoid symptomatology and suffered from *grand mal* as well as psychomotor epilepsy. He had episodes of psychotic paranoid behavior lasting from a few hours to several days. When the patient was symptom-free (Figure 10A), the electrical activity was nearly normal. During the records in Figure 10B the patient was irritable and agitated and had a low threshold for rage. During the recording in Figure 10C he was psychotic, compulsively chanting psalms, detached from his environment, and hallucinating. The stages of pathological behavior are correlated closely with the degree of electrical abnormality in limbic structures.

There is, of course, no reason to expect, even given the peculiar predilection of the limbic system for seizure discharge, that all the pathological processes producing psychoses should be so reflected in neuronal abnormalities recordable with gross electrodes. Nevertheless, the evidence is increasingly clear that in a very high proportion of psychotics such records can be obtained *intracerebrally* and that the focus of such electrical abnormality is in the limbic system.

The psychotropic drugs, which have been so successful in the treatment of mental illness, have profound effects upon the metabolism of the monoamines. In turn, monoamines are found in important concentrations in or above the mesencephalon only in the basal ganglia and limbic system. In addition to being useful in the treatment of psychoses, alterations of monoamine metabolism can also produce psychotic symptoms. Thus, for example, prolonged treatment of hypertension by administration of reserpine not uncommonly results in serious psychotic reactions in previously well adjusted individuals. These patients experience depression; depersonaliza-

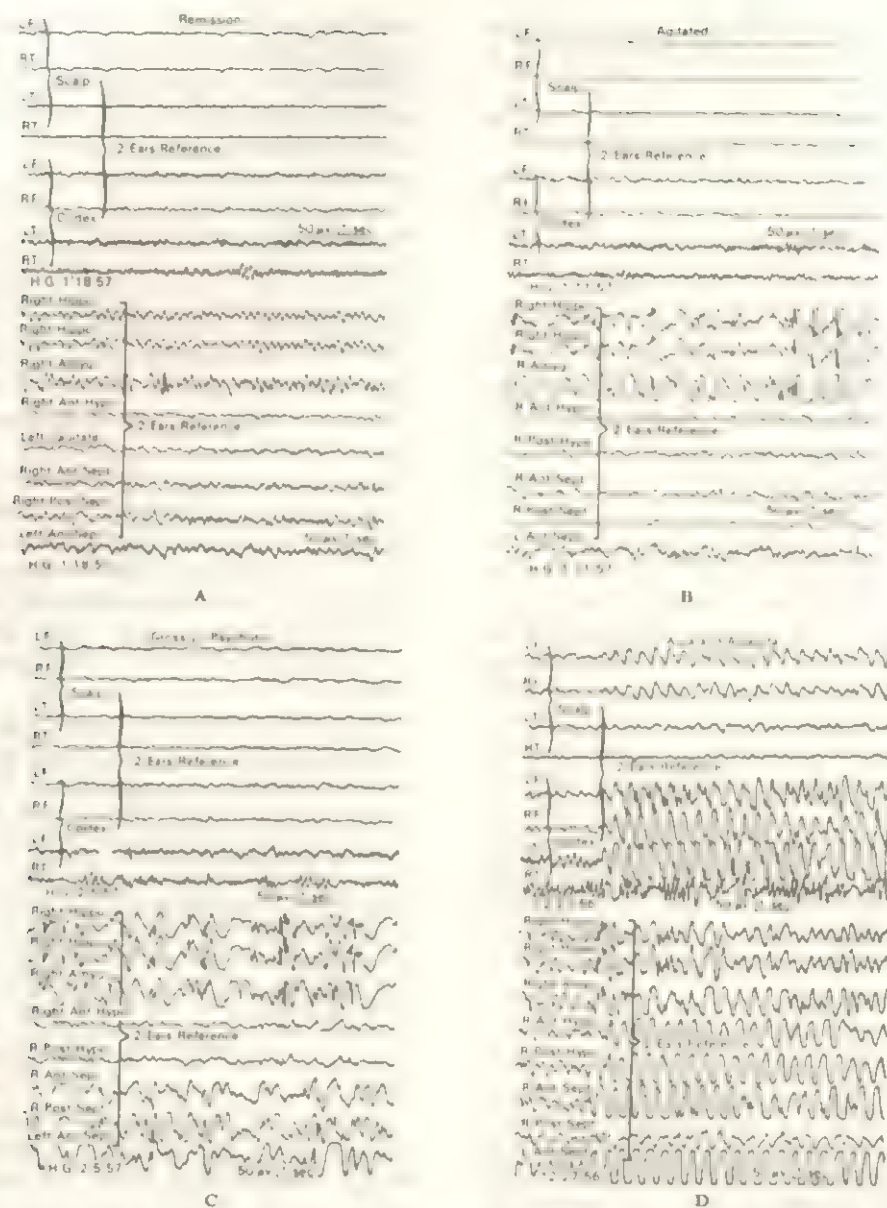

FIGURE 10. Electrical activity in brain of patient whose "psychomotor epilepsy" was accompanied by periodic psychosis. Records from scalp (F, frontal; T, temporal), implanted electrodes over cortex and various leads aimed at hippocampus, amygdala, septum, anterior and posterior hypothalamus, and caudate nucleus. In A, January 10, 1957, patient was symptom free, and records showed essentially normal activity. In B, January 11, 1957, patient was irritable and agitated; records from scalp and neocortex still normal, but convulsive activity apparent in right hippocampus and amygdala. In C, February 5, 1957, patient was hallucinating and reciting psalms; neocortex still normal, limbic system in turmoil. In D, December 27, 1956, psychomotor seizure, neocortex involved; patient complained of bad taste and nausea, and was subsequently amnesic (see the text). (From Heath, R. G. Correlation of electrical recordings from cortical and subcortical regions of the brain with abnormal behavior in human subjects. *Conn. Neurol.*, 18: 305, 1958.)

tion; disturbances of perception, e.g., distortions of size or distance; attacks of terror without reference to external events, etc. These effects can persist for several months after cessation of the reserpine treatment.

In summary, all knowledge gained from stimulating or ablating the limbic system in animals or man is consistent in revealing its power to overwhelm behavior with pathological emotion. Corollary evidence is now forthcoming that both the pathology and ther-

apy of psychotic conditions may be centered on the limbic system.

2.9 CEREBRAL CORTEX

CHARLES J. SMITH, PH.D.

Recovery of Function after Cerebral Lesions

Assessment of residual functions after cerebral lesion is one of the techniques that has been used in order to investigate the functions of the cerebral cortex. Analysis of the functions of the brain would be simpler if removal of an area were followed by a stable loss of a given set of functions. Such is not the case, however, as has been shown repeatedly in both clinical and experimental studies. A loss that may be severe shortly after operation dissipates to a greater or lesser degree over time. This waning of the syndrome following a cerebral lesion has given rise to various propositions about the mechanisms involved. According to the theory of *diaschisis* there is, after a discrete lesion of the brain, a loss of facilitative effects which arose from the destroyed areas and acted upon various intact areas, leaving them in a depressed condition. Recovery from this shock-like state was believed to occur spontaneously over an unspecified time. In attributing function to the area lost by the lesion, only the residual impairment could be used. According to another theory, that of functional substitution or vicarious functioning, other neural centers take over the function of the lost area and substitute for it functionally. Such surrogate areas might include the corresponding area in the opposite hemisphere, in the case of unilateral lesions. This theory gains support from the fact that after a monkey recovers use of the contralateral hand following a unilateral lesion of the motor area,

a second lesion, in the opposite motor area, will produce a re-appearance of paresis. It has been shown that after limited removal of the primary motor cortex a monkey is unable for a time to perform delicate, skilled acts with the contralateral hand. There is considerable recovery from this deficit. If cortex adjacent to the original lesion is then stimulated electrically, hand responses which could not be elicited by electrical stimulation during the first operation are seen. Ablation of this adjacent zone produces a re-appearance of paresis and a second, and more enduring, loss of skilled movements. Bilateral ablations of motor cortex have yielded comparable conclusions. Removal of both right and left primary motor cortex (area 4) in monkeys permits more recovery from motor symptoms than does removal of areas 4 and 6 on the two sides. Many of these principles apply to at least some of the complex behavior found in man, particularly language. There is considerable recovery of verbal function after destruction of frontal cortical speech areas, if remaining cortex on the dominant side of the brain has not been damaged.

When the cortex adjacent to a region ablated in infancy is stimulated, the range of movements elicited is considerably wider than in unoperated control subjects. This has led some to postulate the growth of new pathways, a notion which flies in the face of most data on regeneration in the central nervous system, but which probably should not be dismissed out of hand. A more conservative point of view is that after lesions there are brought into activity pathways which had already existed, but which were not active to any significant degree. The activity of these pathways may have been suppressed by the centers removed. This century-old idea has been made somewhat more palatable by recent neurophysiological demonstrations of inhibition of cells in sensory cortex surrounding an area of high activity, and of greatly increased evoked potentials in some subcortical centers after inactivation of the cortex.

The assessment of recovery of function after cerebral lesions must take account of whether there is substitution of another function similar in purpose to the one lost, or restitution of the original function. The dysphasic patient who manages to construct grammatical sentences, despite a marked vocabulary loss, by use of periphrasis, is substituting, just as is the monkey who solves a puzzle by a different sequence of movements than he did prior to operation. On the other hand, the patient who regains his skill in typewriting after a cerebral lesion, using the same habit skills he used before, such as finger positions, may be said to have a restitution of function. Such a patient would resemble the rat which, after complete bilateral ablation of the visual cortex, can relearn a black-white discrimination at the same rate as it did prior to operation. It is, of course, not always easy or even possible to distinguish the processes of restitution and substitution in any given case or experiment.

Although the theory of *diaschisis* maintained that recovery after lesions was spontaneous, there is considerable evidence that many functions do not recover spontaneously and that training can restore them or speed up their reacquisition significantly. The generality of effect of the training appears to be a function both of the type of skill and of the locus of the brain damage. It has been found, for example, that practice after operation is indispensable for reinstatement of the monkey's ability to solve correctly a patterned string problem after occipital lobectomy on one side. There is no spontaneous cortical reorganization of this task, nor is there wide generalization of the effects of practice. Practice on one pattern will not necessarily transfer to another string problem. After the cortical projection area for central vision is removed in the monkey, there is a transient inaccuracy of reaching for objects. If an operated monkey is kept in darkness for 10 days, he misreaches in just the same way as a monkey does immediately after operation, although nonoperated monkeys kept in darkness for the same period are unimpaired in this reaction. Here again, spontaneous reorganization is at the least unlikely, and visual experience is necessary for recovery.

Experience can influence the outcome of cerebral lesions in

another way. It is frequently found that bilateral removal of homologous areas on the two sides of the brain is followed by a smaller decrement in performance when the operation is performed in two stages than when the operation is carried out all at once. The degree of sparing by the two-stage operation is a function of the stimulation provided the animal in the interval between the two operations. On visual tasks, there is considerable recovery of a brightness discrimination when the subjects are kept in illuminated cages between stages, and complete recovery if the habit is practiced shortly after the first operation. But maintaining the animal in darkness in the interval between operations produces a deficit in visual discrimination performance of the same order as a bilateral, one-stage operation. The slow formation of a pseudofovea in cases of human occipital damage implicates a prolonged period of learning by the patient. In both man and monkey, recovery after occipital injury at maturity seems more a matter of substituting the remaining intact portions of the visual field than one of restitution of function within scotomata.

Recovery from motor lesions is hastened by requiring the animal to use the affected limb, and recovery in cases without formal training may be due in considerable part to the animal's use of the member in negotiating his environment. Recovery from lesions of the motor cortex seems to be somewhat more general than in the case of occipital lesions. The same is true for the temporal neocortex. Bilateral ablations in the temporal area cause loss of visual discrimination habits. If the animals are retrained on visual problems different from the ones they learned prior to operation, retesting on the original problems shows recovery of most of them. Controls show that there is no spontaneous recovery over this period and that visual discrimination habits are not lost if no operation intervenes. Practice on discriminations involving touch have no effect on visual discrimination performance, indicating that the recovery of the habits is not a highly generalized improvement in learning ability after the brain operations.

Effects of lesions as a function of age. The brain of the infant organism differs from that of the adult by having a greater plasticity, as may be seen by the smaller effects of lesions on discriminative and motor performance. Unilateral removal of the primary motor area, the entire frontal lobe, or an entire hemisphere in a baby monkey has much less effect on the motor system than does an equivalent lesion in the mature animal. Bilateral ablation of motor and premotor cortex in the adult monkey has profound effects on volitional movements and produces marked spasticity. The same lesion carried out on the infant has less dramatic effects, and even these dissipate to some extent, leaving as a residual a spasticity which increases with age to about 1½ years. The findings in experiments on sensory discrimination show even less permanent effect of cortical lesions when they are carried out soon after birth. Kittens operated on for removal of the somatosensory cortex showed, as adults, practically no deficit on discrimination of roughness, whereas the same ablation, carried out on adult cats, produced severe impairment of the discrimination. The only residual deficit seen in the case of infant operations was a small increase in the difference threshold. Removal of the primary visual cortex in the kitten, a few days after birth, does not abolish visual pattern discriminations in the adult survivor, even though complete degeneration of the lateral geniculate nucleus establishes that all of the striate area has been removed. Visual function is not entirely normal in such animals, as may be shown by a battery of tests, but the retention of a significant degree of pattern vision is in striking contrast to the complete loss in adult animals suffering extirpation of the entire visual cortex. Optic potentials can be elicited in remaining cortex in such preparations operated on in infancy, and the areas from which potentials can be recorded are implicated in the visual functions which persist, as extension of the lesion to these areas results in extremely poor visual performance on all tasks at maturity. A similar finding in the motor system is relevant to this point. Ablation of the frontal association fields in the monkey, after

bilateral removal of the motor and premotor cortex in infancy, adds to the paresis and spasticity. There is no parallel increment in the motor deficit when the association fields are removed after the motor and premotor areas are taken out in the adult animal. Such observations are consistent with the concept of vicarious function, at least as it may be applied to lesions which occur early in life.

Although not much information is available on the more highly integrated types of behavior, especially in phylogenetically more advanced forms, it has been shown that the delayed response (the classical test for which consists of placing a food reward under one of two covers in view of the subject, then interposing a screen for the delay period, and, finally, allowing a choice between the two food wells), when tested for at 4 months (the time of its first appearance in the normal monkey), is unaffected by lesions of frontal cortex made during the 1st week of life. This response, when tested for in the usual manner, is abolished by lesions made in mature animals. These operated infants, although at first somewhat slower to learn delays as long as 40 seconds, actually surpassed unoperated control animals during the course of an extended series of tests. The often profound effects of cerebral disease in children upon integrative behavior later in life have suggested that certain types of cerebral insult should work greater effects upon young organisms than upon adult ones. Until the specific anatomical differences between the kinds of damage done characteristically by disease in childhood and at maturity are known, experimental approaches to the problem will be impeded.

Cerebral Localization

In the section immediately following, experimental work and some clinical observations are drawn upon in order to indicate in very general terms the functions of various regions of the cerebral hemispheres. The problem of localization of brain function has a long history, and many of the questions raised a century and a half ago remain as pertinent, and unsolved, as they were at their inception. What is localized? Given localization of something, how do the various regions of the cortical mantle work together in an integrated fashion? In the recent past there was a period when localization of anything but the most elementary sensory and motor functions was doubted by many, as a result of overextension of the principles of mass action and equipotentiality. Equipotentiality refers to the ability of any intact part of a cortical system to execute the functions of other parts of that system. This may or may not involve a reduction in over-all efficiency of the system. Equipotentiality is subject in turn to the principle of mass action, which holds that the general efficiency of a complex behavioral function may be reduced in proportion to the extent of destruction of tissue within a system of relatively unspecialized parts. The finding that for the maze habit in the rat the system of relatively unspecialized parts comprise the entire cerebral cortex led many writers of the 1930's and 1940's to suppose that the brain was equipotential for all higher functions and that the law of mass action had quite obliterated functional localization of anything more than muscle twitches or dermatomes.

Although the perplexities of higher brain functions are still with us, we are fortunate in that at the present time localization of function has come into somewhat clearer perspective. The evidence to be summarized below indicates that some functions, especially those most closely related to sensory discrimination and motor control, are rather discretely localized; other traits, such as certain verbal and perceptual mechanisms, tend to be focalized within rather broad regions of the brain. And, in its broadest sense, the organism's over-all capacity to deal effectively with its environment will probably be diminished by any damage to the brain, although some parts may play a proportionately larger role than others. A discrete lesion of the cerebral hemispheres will therefore have a rather specific effect, a somewhat more generalized effect upon some capacity or group of related capacities, and finally a global effect upon integrated behavior.

FIGURE 1. Lateral surface of the right cerebral hemisphere, showing lobes of the brain. (From Truex, R. C., and Carpenter, M. B. *Strong and Elwyn's Human Neuroanatomy*, p. 52. Williams & Wilkins, Baltimore, 1964.)

The most powerful tool available at the present time for analysis of the question of localization of function is double dissociation. By this is meant that lesion A depresses performance I but not performance II, and that lesion B depresses performance II but not I, lesions A and B being of approximately equal size. When this condition is met (and it is more often than not in contemporary studies), functions can be ascribed with some confidence to various regions of the brain. Defining a region is not in itself an easy matter. While size is a readily manipulatable variable, location presents a finite but vast number of possibilities, defying the attachment of a single value to locus as one can with size. In the past the principal guideline for locating a lesion to be made experimentally was the cytoarchitectonic maps of a past generation of neuroanatomists. There has been a tendency more recently to shift from cellular organization of the cortex as a criterion to criteria based upon connections. According to this principle, one removes an area all parts of which have similar connections, whether to some extracortical region or within the cortex itself. These areas may be defined neuroanatomically or by such electrophysiological means as evoked potentials or strychnine neuronography.

Frontal lobe. Although many frontal removals have been done in man for therapeutic purposes, the data available from this source have not revealed a great deal about normal frontal lobe function because most patients were unable to cooperate fully in procedures to assess their status prior to disease. We have many reports on tests applied before operation, but few on tests applied before the onset of the disease which prompted the use of brain surgery. Such data are available in very limited numbers, and they indicate a small but significant loss on formal intelligence tests when premorbid scores (that is, scores obtained before signs of psychosis had appeared) are (1) compared with postoperative scores obtained after the patient appears to have recovered from his psychosis, and (2) evaluated against control patients who recovered without surgical intervention. Despite the inherent superiority of man as a source for data, we must continue to make recourse to animal experimentation to analyze the functions of the frontal areas.

The idea of the frontal lobes as the seat of higher integrative functions has now been abandoned. Ablation studies on mammals high and low on the phylogenetic scale have revealed that, although performance decrements can be shown on certain types of tasks, there is no generalized deterioration. Conditioning experiments show that unconditioned responses elicited by noxious stimuli become more vigorous, and that positive conditioned responses, in which the animal carries out some active behavior in order to avoid the unconditioned stimulus, are either unaffected or even increased after removal of frontal neo-

cortex anterior to the motor zone. Animals are not impaired on visual discrimination learning, nor do they lose a discrimination habit learned prior to operation. The kinds of losses that do occur after prefrontal ablations center around inhibition of responses, and the delayed response. A number of experiments have shown that frontal damage can produce failure to withhold responses when this is demanded for correct solution of the problem. Thus inhibitory conditioned responses in dogs are disinhibited by ablation of the frontal pole, monkeys are less effective in withholding responses on negative trials, and cats show deficits in passive avoidance conditioning (which requires them to avoid approaching an electrified food dish). In all of these cases, the focus within the frontal lobe appears to be the orbital area, as restricted lesions avoiding this zone fail to produce any marked interference with response inhibition.

The delayed response, on the other hand, is selectively impaired by dorsolateral frontal lesions. Recent work has shown that various modifications of the classical method of testing for delayed response enable a monkey with dorsolateral frontal lesions to solve the problem with a high degree of success. These modifications include a "go"-no go" situation (single food well in which the experimenter either places or does not place bait on a given trial; on negative trials the animal must withhold or inhibit its response), gradual introduction of delay, increasing the degree of hunger motivation, and making the correct response dependent upon the subject's pre-delay choice rather than the experimenter's. It has been suggested that these variations of the delayed response experiment show that the crucial element in frontal deficit in monkeys is not delay, but one involving attentional factors operating during the pre-delay period. This finding in the monkey is consistent with the failure to find any deficit of immediate memory in human patients with frontal lobe damage.

Another loss characteristic of the frontal operate is difficulty in overcoming initial preferences in choice situations. Errors made by a frontal lobe monkey in discrimination performance consist not of failure to stick with the correct object when he hits it (by chance) on the first trial, but in failing to switch promptly to the other choice when he selects the incorrect object on the first trial. A similar deficit is found in patients with dorsolateral frontal lesions on card-sorting tasks. The situation differs somewhat in that the patient is required to sort cards according to some category which he must determine by being told whether he is right or wrong. After 10 successive correct sorts, the category is changed by the tester. The frontal patients were unable successfully to shift their sorting sets and consequently committed perseverative errors. The average I.Q. of these patients was normal, and many could verbalize what was

required in the situation, but they persisted in their perseverative (and incorrect) choices.

Parietal lobe. The parietal region of the brain has attracted less experimental work than the frontal and temporal lobes, despite the implication of this region in a number of complex functions in man. Consistent with the presence of the primary somatosensory area in the parietal lobe, tactile discrimination performance by monkeys and apes is impaired by lesions in this region. There are, however, functions beyond these simple somatosensory discriminative ones which may be demonstrated by the placement of lesions. Monkeys with unilateral lesions of the posterior parietal lobe failed to reach food by an approach on the side opposite the lesion when a roundabout route was required. When visual cues were excluded, the inability to reach the bait on the side opposite the lesion was relatively less. This finding suggests that the posterior parietal lobe may be concerned with the coordination of visual cues with purposeful movements, an hypothesis consistent with anatomical data indicating that fibers from the occipital lobe end here and that the posterior parietal area projects in turn to both the somatosensory and motor areas. The hypothesis of visually related functions in the parietal lobe receives further support from the finding that extensive learning experience with tactile stimuli fails to facilitate performance on a visual learning set series in monkeys with posterior parietal lesions. Even more straightforward visual spatial discriminations are impaired to some extent by bilateral posterior parietal ablations. Careful observations on patients with long standing parietal injuries has shown, in addition to the expected tactile sensory losses, an impairment in the ability in patients with left parietal injury to indicate successively a series of points on the body surface and in external space. Lesions of either side, located predominantly in the parietal zone, produce an impairment in the ability of patients to follow a map, using either tactile or visual cues. This deficit is independent of sensory defect or of losses in general intelligence, although the degree of impairment is correlated statistically with somatosensory defect. There is extensive evidence that, whereas injury in man's right somatosensory region produces difficulties related only to the left hand, left somatosensory lesions tend to produce bilateral impairment. Injuries to the left hemisphere are more likely to be associated with dysphasia and with a greater intellectual loss than right hemisphere injuries.

Temporal lobe. Experimental lesions in primates have demonstrated conclusively that a major focus for visual integration exists in the temporal lobe. Tests for discrimination of patterns show a persistent loss after bilateral removals of the inferior convexity of the temporal lobes, a loss which is not found after lesions of the dorsolateral temporal neocortex or other associative areas of the cortex, nor after removal of temporal pole, hippocampus, or amygdala. Long term studies of operated monkeys indicate that this loss is very persistent and probably permanent. The degree of loss is correlated with the difficulty of the problem, the greater impairments being most clearly demonstrated by difficult discriminations. When animals are trained successively on a large number of pattern discrimination problems, establishing a learning set, and are then subjected to bilateral inferotemporal removals, the learning set is lost and cannot be regained with extensive retraining. Object discriminations are less affected by temporal lesions, although some impairment is seen. This deficit does not seem to be one of attentiveness, as monkeys with temporal ablations continue to discriminate even when the stimuli are exposed for as short a time as 10 milliseconds. The probable route for arrival of visual information to the temporal lobe is via the primary visual cortex of the same side of the brain. Interruption of visual afferents to the striate cortex by cutting of the optic tract, followed by ablation of temporal cortex on the opposite side, produces a marked impairment in visual discrimination. Such an impairment does not occur when the optic tract and temporal lobe are interfered with on the same side of the brain. Lesions of possible subcortical routes to the temporal lobe, such as superior

colliculus or pulvinar, fail to duplicate the temporal lobe discriminative loss, giving additional support to a neocortical relay from the visual cortex.

Temporal removals in man indicate a laterality difference of function as strong, possibly stronger, than that found in the parietal region. Although the over-all I.Q. seems to be little affected by unilateral temporal lobe operations, there are difficulties in verbal recall, especially of rapidly presented material, when the lesion occurs on the left side. Right-sided temporal operations, on the other hand, are associated with inefficiency of comprehension of pictorial material. Memory defects, when seen in association with temporal lobe damage in man, seem to be referable strictly to rhinencephalic structures. Ideomotor and ideational apraxia are predominantly, perhaps exclusively, associated with left or bilateral damage to the temporal zone. Tachistoscopic recognition is also affected differentially. Recognition of letters is poorer in the visual half field opposite the side of the lesion, but since in normal subjects such recognition is not so good in the left field as in the right, one may conclude that right-sided lesions impair both half fields, whereas lesions on the left side give a deficit only in the right visual field. Thus the right temporal neocortex participates to some degree in visual functions through the entire visual field. So far there is no indication of similar right-left differences in experimental animals.

Occipital lobe. Research on the occipital lobe in man and animal has focused upon visual field defects after lesions. There are a few observations which suggest strongly that more than field defects are involved, but unfortunately they have not yet inspired well controlled studies to clarify the nature of the mechanisms that may be involved. It was noted long ago that ablations of the rat's visual cortex produce losses on maze performance which cannot be duplicated by peripheral blinding, and more recent work on peripherally blinded monkeys indicates that they too are impaired in finding their way about after extensive lesions of the primary visual cortex. Lesions in man (which may extend beyond the confines of the striate area) have been associated with deterioration of subtests of intelligence tests, particularly digit span and arithmetic problems. Studies such as these indicate that the striate cortex has non-visual functions, just as "nonvisual" cortex (the temporal lobe, for example) has visual functions. Visual field defects are particularly difficult to map in experimental animals, so that one may expect that studies on patients after occipital injury will be the more fruitful avenue of approach.

Suggested Cross References

In this section some fundamental concepts of cortical functioning have been discussed, but no attempt was made to describe and localize all the known functions. For a more complete summary of the cerebral functions and their locations, see the chart following this section. For a discussion of tests of mental status, the neurological examination and tests for organic brain disorders, all of which are based on assessment of cerebral functions, see Sections 11.2, 10.1, and 12.2, respectively. The cerebral cortex is discussed from the viewpoint of clinical neurology in Chapter 10. The symptoms seen in organic brain disorders are mainly disturbances of the functions of the cerebral cortex, and these are discussed in Chapters 18 to 21 and in Section 42.3.

SUMMARY OF FUNCTIONS OF THE CEREBRAL CORTEX

SEYMOUR SOLOMON, M.D.

FIGURE 1. Cytoarchitectural map of human cortex. A, convex surface; B, medial surface (after Brodmann). (From Truex, R. C. and Carpenter, M. B. *Strong and Elwyn's Human Neuroanatomy*, ed. 5, p. 469. Williams & Wilkins, Baltimore, 1964.)

The numbers referred to below are those corresponding to Brodmann's cytoarchitectural map of the cerebral cortex (see Figure 1). These numbers are used *only* for simplicity of identification. Functions cited are not as precisely localized as indicated by the map; localization of aphasic phenomena are par-

ticularly inconsistent in this respect. The defects described in the last column are due to destructive unilateral lesions unless otherwise stated. As a rule, an irritative lesion evokes a focal seizure, augmenting or altering the function of the affected area.

Lobe	Area	Function	Effect of Lesion
Frontal	Primary motor area (4)	Initiate voluntary movement	Initial contralateral flaccid palsy of skeletal muscles; later, spastic paresis
	Secondary or premotor area (6)	Organize and control voluntary movement	Contralateral spastic palsy or paresis of skeletal muscles
	Transitional area between 4 and 6 (4S)	Inhibit motor activity	Spasticity of contralateral somatic musculature
	Motor eye field (8, 46?)	Control voluntary conjugate eye movement	Initial but transient deviation of eyes to side of the lesion and palsy of gaze to the opposite side (deviation of eyes away from irritative lesion)
	Speech area—Broca's area (44, 45?) (<i>dominant hemisphere</i>)	Control expressive speech	Motor aphasia
	Association areas or prefrontal lobe (9, 10, 11, 12, 32, 47)	Govern high intellectual processes and emotions	Mental and emotional symptoms, such as psychomotor retardation, lack of concern, <i>witzelsucht</i>
	Cingulate region (24, 25, 33)	(See temporal lobe)	(See temporal lobe)
	Poorly defined areas in motor and premotor cortex (4, 6, and adjacent zones) give rise to frontopontocerebellar pathways	Permit smooth voluntary and automatic skeletal muscle movement	Contralateral ataxia and other cerebellar signs
	Poorly defined areas throughout the prefrontal lobe (9, 10, 11, 12, 32, 47) give rise to connections:		Areas too diffuse for focal lesions to cause specific dysfunctions
	(a) to basal ganglia	Elaborate voluntary and automatic movement with cerebellar centers	
Parietal	(b) from thalamus and to hypothalamus	Integrate and elaborate stimuli for highest prefrontal functions	
	Primary sensory area (1, 3, and, minimally, 2)	Receive, identify, and localize simple somatic sensory stimuli	Contralateral impairment of somatic sensory modalities
	Secondary association area (5 and, especially, 7)	Further integrate, synthesize, and elaborate somatic sensory impulses, such as stereognosis	Slight contralateral impairment of somatic sensory modalities; astereognosis
	Posterior aspect of area 7	Further integrate somatic sensory impulses; discriminate fine grades of somatic sensation	Slight contralateral somatic sensory impairment; contralateral astereognosis, inattention (extinction phenomenon), trophic lesions
	Areas 39 (angular gyrus) and 40 (supramarginal gyrus)	Integrate visual and auditory stimuli with somatic sensory impulses	<i>Dominant hemisphere:</i> receptive aphasia; sometimes alexia, agraphia, or defect in body scheme
	Cingulate region (23, 31)	(See temporal lobe)	(See temporal lobe)
	Subcortical: optic radiations deep within the parietal lobe	Carry visual impulses	Contralateral homonymous inferior quadrantanopsia or hemianopsia
Temporal	Primary auditory receptive area—Heschl's gyrus (41, 42?)	Receive auditory impulses	No deficit because of bilateral cortical representation

Lobe	Area	Function	Effect of Lesion
Occipital	Auditory association area (22, 42, 52?, and adjacent areas)	Form memory patterns, especially for symbolic sounds, and may receive vestibular impulses	<i>Dominant hemisphere:</i> receptive aphasia
	Olfactory areas (28 and 35)	Receive olfactory impulses	No deficit because of extensive bilateral representation
	Gustatory areas unknown and may even be beyond the temporal lobe, such as in area 43	Receive gustatory impulses	No deficit because of extensive bilateral representation
	Association areas (20, 21, 36, 37, 38) make connections with cortical areas of frontal, parietal, and occipital lobes	Form memories and take part in other intellectual and emotional phenomena	Little or no deficit because of extensive cerebral representation
	Cingulate region: areas 26, 29, 30—temporal; 23, 31—parietal; 24, 25, 33—frontal; subcortical structures of the limbic system	Control visceral phenomena, sexual activities, and emotions	Personality changes [<i>Temporal lobe in general: Psychomotor seizures with irritative lesion of any part; memory impairment, Korsakoff-like syndrome or modified Klüver-Bucy syndrome with bilateral lesions</i>]
	Subcortical: optic radiations in the temporal lobe	Carry visual impulses	Contralateral homonymous superior quadrantanopsia
	Primary visual receptive area (17)	Receive visual impulses	Contralateral homonymous hemianopsia with macular sparing; cortical blindness with bilateral lesions
	Parareceptive area (18) Preoccipital area (19)	Interpret visual impulses Form visual associations: perception, orientation, recall Both areas 18 and 19 take part in optically induced reflexes	Disturbance of spatial orientation and discrimination, visual agnosia, illusions, and hallucinations Transient conjugate deviation of eyes toward the side of the lesion

2.10 NEUROPHYSIOLOGICAL CORRELATES OF LEARNING AND MEMORY

E. ROY JOHN, PH.D.

The purpose of this section is to acquaint the reader with the broad outlines of present knowledge and current research related to problems of information storage and retrieval in the brain. Although space does not permit a more detailed presentation, the current understanding is inadequate for a definitive exposition.

Two types of processes can be distinguished in the functions of the nervous system—innate and acquired. Innate processes display essentially similar characteristics in all individuals of the same species, follow the same maturational course, and are probably mediated by approximately identical mechanisms from individual to individual. Innate processes subserve the essential functions necessary to maintain the health and integrity of the organism, fulfilling requirements

common to all members of a species. Acquired processes vary greatly among individuals of the same species, do not follow the same maturational course, and may be mediated in radically different ways by various individuals. Acquired processes permit the individual to adapt to, and benefit by, his unique personal life experiences. The nervous system is thus endowed with plasticity of response, enabling the organism to establish adaptive behaviors. Behavior can be altered by changes in the novelty of stimuli, by the results of environmental events or particular responses, and by associations based upon the similarity, dissimilarity, or contiguity between exteroceptive or interoceptive stimuli. These and other changes in behavior resulting from the accumulation of experience are classified as *learning*.

Learning, or defects in learning, can result in maladaptive as well as adaptive behaviors. Many psychiatric disorders may be the result of inappropriate learning, undesirable experience, or malfunction of the neural mechanisms of information coding, storage, and retrieval. Other disorders which seem related to malfunction or imbalance of neural systems concerned with arousal, attention, or motivation may be amen-

able to procedures that use systematic experience to improve function or restore balance. Much of psychiatric treatment can be viewed as the attempt to establish conditions conducive to learning adaptive behaviors, or unlearning maladaptive behaviors, whether achieved by electroconvulsive therapy, medication, or psychotherapy.

Theories of Learning and Memory

Since learning requires the modification of future behavior as a result of past experience, two distinct processes must be explained: (1) the neural mechanisms involved in storage of a representation of an experience and (2) the neural mechanisms that are intermediaries in the retrieval of such stored information and its interaction with present experience. The first function might be called "read in," or memory, and the second "read out," or remembering.

Classical conditioned reflex. Early attempts to analyze the nature of these processes were strongly influenced by anatomical considerations. The laboratory study of the physiology of learning consisted largely of investigations of conditioned reflex mechanisms. The classical conditioned reflex arises from the association of two stimuli and can be thought of as stimulus substitution.

A conditioned stimulus that excites sensory receptors is systematically paired with an unconditioned stimulus that activates muscular or glandular effectors. After a series of paired presentations, occurrence of the conditioned stimulus alone is capable of eliciting a conditioned response closely resembling the effect of the unconditioned stimulus. The conditioned stimulus was presumed to activate neurons in brain regions of the corresponding receptor system and the unconditioned stimulus to activate neurons localized in regions that mediated the appropriate response functions. Paired presentation of conditioned stimulus and unconditioned stimulus was assumed to result in the formation of a connection between these two neural regions. This connection consisted of a pathway of neurons whose synaptic relationships were altered during conditioning, either by facilitation of existing synapses or by the growth of new synaptic processes. The memory was localized in the interconnections of the neurons constituting this pathway. Remembering consisted of the selective conduction of nerve impulses arising from the conditioned stimulus along this new pathway to the regions previously excited by the unconditioned stimulus, thus eliciting performance of the conditioned response. Similar explanations were proposed to account for other forms of learning, such as instrumental conditioned responses or maze habits, analyzed in comparable stimulus-response terms.

Attributing changes in behavioral response, after experience, to the establishment of new neural routes traversed by nerve impulses initiated by stimuli led to a search for the anatomical locus of the site of closure and for the connection between the input and

output pathways, which was the memory or engram. The fundamental tool in this search for a connection was the correlation of deficits in the acquisition or performance of learned responses with lesions or ablations localized in various brain regions.

Lashley's general theories. Although lesion studies revealed that particular brain regions were involved in the mediation of learned responses, it was not possible to demonstrate that memories were localized in specific areas or pathways. Deficits in performance following brain damage could usually be rectified by further training of lesser degree than that required for the initial establishment of the behavior. Interference with the set to perform, with motivation, with attention, or with level of arousal seemed to constitute the basis for such deficits, rather than obliteration of the memory trace.

Summarizing a vast amount of lesion data, Lashley proposed two related general theories: (1) the Law of Mass Action, which proposed that defects following brain ablations correspond in severity to the amount of tissue destroyed rather than to the location of that tissue; and (2) the Law of Equipotentiality, which held that, although a given region may normally be responsible for mediation of a given function, other regions are often capable of taking over the same role.

Memory storage and retrieval. Implicit in Lashley's formulations was the conception of memory as a process diffused throughout an extensive anatomical domain. Further, experiments revealed that the effects of localized lesions varied as a function of time after acquisition of the new behavior. These experiments suggested that different brain areas became involved at *different stages* in the elaboration of a memory. In particular, the hippocampus seemed to be involved in the process by which recent events were transferred to permanent storage.

It has long been known that the ability to remember lists of memorized material varies as a function of the amount and kind of activity interpolated between initial learning and subsequent testing. Systematic study of sufferers of traumatic head injury revealed that a large proportion of such persons could not recall events immediately preceding the injury. Evidence of this sort suggested that, immediately following an experience, the neural representation of that event was in a labile phase and was susceptible to disruption; after this period, the memory was somehow stabilized in long term storage. With the introduction of electroconvulsive shock therapy, studies revealed that the disruptive effects of such treatment upon recent memories diminished systematically as a function of the time between experience and shock.

Numerous studies have indicated that interference with ongoing brain activity for a period of time after an event prevents registration of that event in memory. Among the agents capable of such action are elec-

troconvulsive therapy, anesthetics, convulsions induced by various chemical agents, and insulin hypoglycemia. This evidence had led to the concept of a consolidation phase, during which the neural representation of an experience gradually shifts from a labile to a stable mediating process. Recent studies have shown that systemic injection of analeptic drugs immediately after an experience can extend the period of labile representation, can bring about more rapid acquisition of learned responses, and can accelerate the rate of consolidation.

It is generally believed that the representation of an experience during the labile phase is mediated by continued reverberatory activity in neural networks. The mechanism responsible for long term storage is the subject of intensive current research.

Chemical studies. The remarkable persistence of memory in spite of the relatively rapid turnover of chemical compounds in the brain directed the attention of numerous investigators to those chemical systems capable of specifying templates for the continued synthesis of particular molecules, ribonucleic acid (RNA) in particular. A mass of evidence accumulated in recent years suggests that ribonucleic acid and protein synthesis are somehow involved in long term information storage in the brain. It has been shown that (1) RNA turnover in nerves increases upon stimulation, (2) RNA turnover is increased in neural tissue that undergoes learning-like experiences, (3) interference with RNA synthesis impedes learning, and (4) facilitation of RNA synthesis or increased availability of RNA results in more rapid learning.

Although such evidence suggests that RNA is involved in memory storage, the demonstration that the blockade of protein synthesis by intracerebral puromycin injection may erase previously established learned responses suggests that the role of RNA may be secondary to that of the protein whose synthesis is governed by RNA. Although puromycin blocks protein synthesis, present knowledge indicates that it does not in any way interfere with RNA synthesis. Further research is needed to clarify this problem.

Electrophysiological studies. Such studies, usually conducted with chronically implanted electrodes, show that there are widespread changes in the response of brain regions to a stimulus during learning. These changes involve many anatomical systems in the brain. The data suggest that, early in learning, the stimulus exerts marked effects upon the mesencephalic reticular formation. Later in learning, the thalamic reticular system seems to play a dominant role, while the mesencephalic reticular formation seems to be inhibited, perhaps by hippocampal influences interacting with the cortex.

Among the useful electrophysiological techniques are the biasing of local excitabilities by polarization (so-called dominant focus), studies of evoked potential changes to intermittent conditioned stimuli, and conditioning to direct electrical stimulation of

specific points in the brain. Such methods, combined with such chemical techniques as spreading depression and classical ablation methods, as well as the more recent split brain technique, can be expected to provide a steady increment in understanding of memory storage and retrieval mechanisms.

Electrophysiological studies with intermittent conditioned stimuli have revealed that the brain seems to possess the capability to reproduce previously experienced, temporal patterns of activity. Under particular conditions, the electrical activity of the brain seems to contain two components: exogenous activity, arising from stimulation of sensory receptors, and endogenous activity, related to previous experience. Endogenous activity is particularly noteworthy in nonsensory specific regions of the brain. Various writers have suggested the existence of a coincidence detector system, in which exogenous activity in sensory specific pathways is compared to endogenous activity released in nonsensory specific regions by the afferent input from the stimulus.

Neutral stimuli have been reported to release endogenous activity patterns together with concomitant behavioral performance of previously acquired responses. Such released patterns can arise at different anatomical levels and do not appear to be a property of a localized region. Evidence of this sort suggests that memory may be mediated by a widely distributed mechanism capable of initiating particular patterns of activity in large neural aggregates. Much further work will be necessary to evaluate the functional significance of such phenomena.

Suggested Cross References

For a description of the anatomy and the functions of the neural structures referred to in this section, see Sections 2.5 to 2.9. Bachrach's section on learning theories, Section 3.3, contains a more extensive discussion of current concepts of learning. For a discussion of the application of concepts derived from learning theory to the practice of clinical psychiatry, see Urban and Ford's section on behavioral therapy, Section 34.2, in Area G, on treatment.

Chapter 3

BASIC PSYCHOLOGICAL SCIENCES

3.1 ✓ PERCEPTION

CYNTHIA P. DEUTSCH, Ph.D.

Definition

Perception, according to a generally acceptable definition, is "...the process of organizing and interpreting sensory data by combining them with the results of previous experience." This definition contains several elements which give it its distinction. First, the term "process" implies that perception is not the name of a static structure or property of an organism but of an activity. Thus perception is something that is going on. The second element to be noted is the naming of the process that is going on: "organizing" and "interpreting." These words indicate that the process is an active one, and one which involves the organism in acting on something. The third element tells what that something is: "sensory data." Sensory data, in turn, may be defined as the uninterpreted product of the stimulation of end organs, or receptors, such as the eye or the ear. The last element is the entire last phrase of the definition, "...by combining them with the results of previous experience." The "combining" again indicates that it is an active process which is going on. The "results of previous experience" brings in another activity: *memory*. This element in the definition implies, then, that without memory and without bringing the memory to bear on the sense data, there is no perception. It also implies that without previous experience there is no perception. (This last point will be discussed again in the examination of some theories of perception; for now, however, let its implication stand.)

This definition indicates, then, that perception is a complex process involving the past as well as the present, and involving an external stimulus as well as an internal response. This fusing of past and present, of external and internal, makes perception a complex area, and its complexity accounts for the fact that many different theories of perceptual processes have arisen.

Scope

Perception, like the science of psychology itself, stretches from the biological sciences on one side to the social sciences on the other and includes data and ideas from physics and philosophy as well. The study and understanding of perceptual processes include these four broad fields.

Epistemology, that branch of philosophy which asks the question "How do we know?" sets the question which the study of perception endeavors to answer. The answer involves the physical properties of stimuli, the individual's nervous system, and his background and experiences. The physical properties of stimuli—wave lengths of light, frequencies of sound, and the like—are fundamental in determining the nature of the sense data. The individual's nervous system is the locus of the sensation and the perception, and its functional strengths and deficiencies relate to what is sensed and what is perceived. And the individual's family background and general social milieu and experiences contribute to his interpretation of his sense data.

For example, say a group of people, one by one, look through a small aperture at a green light. Afterwards, each one is asked what he saw. One subject says, "I saw a light, but I can't say any more about it." What might be the explanation? It could be explained by any of the aspects described above. For example, it might be that when he looked through the aperture, something went awry with the transmitting apparatus, the wave length of the light changed several times, and he experienced a variety of colors subjectively. Or it might be that the subject was color-blind, having a physiological or anatomical disorder involving certain of the sense cells of the retina. Or it might be that he had never been taught color names or the differences between colors, an example of social factors at work. Just as the descriptions of an elephant by several blind men were determined by which part each man felt, so a view of perception could be determined by which aspect is emphasized. The goal must be to mesh all aspects into an understanding of the whole. Especially is this important when one is attempting to evaluate an individual's perceptions—and aberrant perceptions.

External Stimuli

In considering the external stimulus, we must first of all be aware that there are various sense modalities through which organisms are stimulated, and that the sense organ which is stimulated yields only a particular type of sensation. This last point was enunciated first as the doctrine of the "specific energy of nerves" by Johannes Müller in the 19th century. This was an important milestone in the path to modern considerations of perception, as it spelled the end of the concept of the transmission of entire images from the external environment to the brain. As long as the idea was generally held that an object such as a pencil was transmitted, as it were, whole, from the external world into the brain, there was little opportunity to investigate the components of sensation and of perception and the components of the attribution of meaning to sense data. When that idea was replaced by the notion that each set of nerve fibers transmitted impulses which were consistently and characteristically sensed in particular ways, it became clear that what was received was a set of sensations having to do with dimension, form, color, and similar attributes of the object. Through experience, the individual learns that that particular configuration of attributes is called a pencil. With this understanding, the whole area of sensation and perception as we now know it was opened to study.

Deriving from the doctrine of the specific energy of nerves is the categorization of "adequate stimuli" for each sense modality. Thus, sound is the adequate stimulus for the ear and the acoustic nerve complex, light for the eye, and so forth. A physical analysis of a given environment could determine the particular modality that would be stimulated in it.

Visual stimuli. A great deal of the work on the influences of the stimulus field in perception has been done in the visual area. This is probably because what is perceived visually is strongly determined by the ordering of the stimulus components in space, and this is rather easy to manipulate. For example,

* * * * *

is a row of 16 asterisks. By manipulating the spatial relationships, one can enhance the probability that they will be seen as 8 pairs of asterisks:

* * * * *

In this pairing, the first and second, the third and fourth, and so on, constitute pairs. It is quite difficult to see the first as a single asterisk, with the second and third, and the fourth and fifth, and so on, being the pairs. Yet this perception can be encouraged by changing the spaces again:

* * * * *

It can also be done by adding another formal element and returning to the earlier spacing:

* * * * *

In simple experiments such as these, what is perceived depends upon and varies greatly with the

grouping and the spacing of the individual stimuli. Analogies can be drawn in audition: the same set of tones will be heard as different melodies, depending on the timing and spacing of their presentation.

Motion pictures provide another example of how perception is determined by the organization of the stimulus field. The stimulus of the motion picture is, of course, not motion per se but a series of still pictures taken at very short intervals. The intervals between the pictures taken determine how fast the movement appears to be: the longer the interval between pictures during filming, the faster and the less smooth the movement seems when the pictures are projected. Slow motion films are actually those in which the camera action is the fastest; there is, for instance, the least excursion of a moving extremity between successive pictures. Seeing the subjects of the pictures move is a perceptual phenomenon called *Phi* phenomenon or apparent motion. Another example of apparent motion is the moving sign in which a light appears to go around the edge of a marquee, but the physical stimuli are really a great many electric bulbs being switched on and off in sequence.

Such situations, in which what is perceived is based on physical stimuli but is different from them, led to the enunciation of a principle to the effect that *the whole is different from the sum of its parts*. One explanation of this principle defines stimulus organization, or *Gestalt*, as an additional property of the stimulus field.

Selectivity. Since man has receptors for many types of stimuli and since he lives in a complex environment in which there are numerous varieties of stimuli, he is constantly being stimulated. In fact, in the usual environment, far more stimuli than the individual can be aware of or respond to are impinging on him at any given instant. While these stimuli are impinging simultaneously through many different channels—sound through the ear and along the acoustic nerve and its connections to the central auditory projection areas, light through the eye and along the optic pathways, etc.—the *perceptual process is a central one*, and only a limited amount of this vast information can be processed at one time. Therefore, a process of selectivity becomes operative. Some stimuli are perceived and some are not; some that are perceived are responded to and some are not.

Some objective and many subjective factors govern the operation of this selectivity; both the stimulus field and the attributes of the perceiver determine what will be perceived. One important objective factor is the strength of the stimulus: typically, a strong stimulus is more likely to be perceived than a weak one. When two noises are present in the environment at the same time, the louder noise will mask the softer one. And usually (though not inevitably) a stronger stimulus in one modality will be perceived in preference to a weaker one in another modality.

Thus, a very bright light may diminish the perception of a low sound. Another objective factor that governs what is perceived is timing: a stimulus that begins an instant before another may be perceived at the expense of the second, although the relative intensity of the two stimuli must also be considered. And there is a paradigm visual perceptual experiment that demonstrates that a particular type of stimulus can distort the perception of a *preceding* stimulus so that the earlier one is not perceived as it was presented. The nature of the fibers that transmit the impulse can also determine the order in which stimuli are perceived. If one touches a very hot surface, he will usually feel the heat first and then the pain because the fibers that transmit the heat sensation carry impulses faster than do the pain fibers.

Other factors that determine which of a variety of impinging stimuli will be perceived have to do with the neurophysiology of perception and sensation and with individual experience and learning.

Neurophysiology of Perception

In the exploration of the neurophysiology of perception, we move away from emphasis on the stimulus field as a determiner of what is perceived. The first step is the response of the end organ to stimulation from the field. It is not appropriate here to discuss the anatomy or the basic physiology of the sensory pathways or to do more than note in passing that the intactness of the sense organs and tracts is a necessary condition for accurate perception. As noted in an earlier example, color blindness will interfere with the perception of color. Similarly, diminished auditory sensitivity to particular frequencies will distort the perception of sound. The nature of such distortions and their relationship to various types of sensory disabilities will not be discussed here.

However, the perception of physical stimuli involves more than simply the sensory pathways specific to a particular modality of stimulation. Recent work has placed considerable emphasis on the role of the reticular formation in the perception of stimuli. This activating system is apparently essential to the arousal of the organism, which must precede the reception of a stimulus from any modality. The work of Magoun and his associates indicates that when the reticular pathways of an animal are cut, the animal is rendered insensitive to stimuli that normally produce arousal and response. The full role of the reticular activating system is not yet known, but the evidence is such that it can be safely accepted that this system plays a critical role in the perception of stimulation, probably through its effect on general arousal and on attention.

Neurophysiological factors, it has been hypothesized, enter into the selectivity of perception through the reticular activating system. An experiment by Hernández-Peón illustrates this. He placed electrodes in a cat's cochlear nucleus in the brain stem and re-

corded the evoked potential in response to the presentation of clicks. That the cat's sensory apparatus was being stimulated by the clicks was evident from the evoked potential record. However, when a mouse was placed in the cat's visual field, the evoked potentials disappeared from the electrographic record, even though the clicks were still being presented. The cat's visual attention to the mouse—a very compelling stimulus for a cat—superseded its aural attention to the clicks, which were apparently not even noted in its brain. In one interpretation, this experiment shows the importance of the activating system in the perception of stimuli and indicates that selectivity in perception can have a strong neurophysiological component. There has been some theoretical argument about the strength of this interpretation, but the facts of the experiment are unassailable.

A different type of experiment relating to the selectivity of perception was done by Cherry. He presented differing stimuli to each of the subjects' two ears and asked them what they heard. He found that "irrelevant" information is rejected in favor of "relevant": the subjects could not report the irrelevant stimuli fed to one ear, but they could follow the directions presented to the other ear. However, he also found that a "noisier" noise masks the perception of a more meaningful one.

Individual Development and Experience

Let us now consider the influences on perception which arise from individual development and experience. One tends, for example, to perceive the more important stimuli rather than the less important. Since the attribute of importance is based on individual experience and interests, two people in the same situation may perceive very different things, and yet both may be accurate. What each perceives is a function of his own learning and experience. This is true in terms of both long term and short term experience. For example, the letter "A" would be simply a collection of lines for someone who does not know how to read. But for someone who did, seeing the "A" as a letter would inhibit perception of the letter's individual lines. A particular experience could invest the percept with additional meaning, as, for instance, the special meaning of the letter "A" to Hester Prynne in *The Scarlet Letter*.

The short term influence of experience on perception can be illustrated by an experiment that presented the same rather ambiguous figure to two groups of subjects. The figure could be seen as most resembling either a pair of eyeglasses or a dumbbell. On the initial presentation, one group of subjects was told that it was a picture representing eyeglasses; the other group had its attention called to the dumbbell characteristics of the figure. When both groups were later asked to reproduce the figure, the first group emphasized the eyeglass properties, while the second emphasized the dumbbell characteristics. Since the figure

presented to the two groups was the same, the differential interpretation of it—the different perceptions of it—could be attributed only to the differential short term experience.

An experience that predisposes an individual to certain types of perceptions is called a set. The influence of set on perception has been quite extensively studied, and several groups of principles have emerged. One large group of principles concerns the properties of the stimulus. The prototype principle here is that the more ambiguous the stimulus, the more will its perception be determined by the set or proclivities of the subject. Another group of principles concerns the properties of the respondent. The prime example here is that the stronger the set of the individual, the more will it determine his perception. When the two groups of principles interact, what emerges is the proposition that the meaning attributed to a particular stimulus by an individual is a function of the ambiguity of the stimulus and the strength of the individual's set.

Application of Principles

These principles have been extensively applied in studying individuals. By presenting unambiguous stimuli and analyzing incorrect responses, one can get a rough measure of the strength and nature of sets of particular subjects. This technique has its greatest application in the evaluation and study of individuals who show considerable distortion in their perceptions of the world around them.

Projective tests. The major application of these principles, however, has been in projective testing, in which ambiguous stimuli are presented to individuals and their responses are analyzed in terms of their emphasis and patterning. Extrapolated from this analysis is a description of the individual's personality in terms of his perceptual proclivities. Perhaps the best known projective test is the Rorschach test, which is a collection of 10 inkblots. These are, of course, highly ambiguous stimuli that are in themselves meaningless. The individual is shown each inkblot and is asked the question, "What does this remind you of?" His responses are categorized according to a developed system and then interpreted in terms of his personality structure. Hermann Rorschach, the originator of the test, considered it a perceptual experiment, and it does, indeed, make use of one of the basic assumptions about the determination of what is perceived: that a percept is a function of the ambiguity of the stimulus and the strength of the individual's set.

The needs of the individual also influence the content of what is perceived. A classic experiment in this area presented ambiguous pictures to a group of college students 1, 3, 6, and 9 hours after eating. The incidence of food and food-related perceptions was lowest 1 hour after eating and increased in their reports 3 and 6 hours after eating; it decreased some-

what at the 9-hour testing but remained higher than at the 1-hour test. Another experiment showed that hungry subjects judged food objects as larger than other ambiguously structured stimuli.

Over-all psychological needs as well as immediate physical needs influence perception. Another well known projective test, the Thematic Apperception Test, or TAT, is based on this proposition. The stimuli for this test consist of pictures of people in various situations. The situations are ambiguous enough to allow for a variety of interpretations. The subject is asked to tell a story about each picture, and his story is interpreted in terms of his particular needs and drives. The test yields information about the individual's personality through an analysis of his need structure.

Studies of individual perception. Emphasis on analysis of responses to stimuli as a means of learning about the individual is seen in a now classic series of experiments by Witkin and his associates. The basic experimental task in the series was adjusting a rod so that it would be exactly vertical within a frame. The experiment was usually carried out in the dark, with the rod and the frame painted with luminous paint. Numerous variations were introduced. For instance, in some experiments the frame was presented at an angle; the subject could then adjust the rod to make its position consistent with the presumed verticality of the frame or with other cues to the dimensions of the environment, such as his own bodily orientation in space. These latter variables were also manipulated; in some experiments, the subject sat in a tilting chair. By comparing the rod's direction and degree of deviation from the vertical, the experimenter was able to determine which cues the subject used. A series of studies then investigated correlations between personality traits and types and the cues relied on to adjust the rod. Subjects who relied mainly on the position of the frame to judge the vertical were labeled "field-dependent"; those who relied in the main on cues coming from their own body position were called "field-independent." The field-dependent subjects tended to make greater errors in the estimation of the vertical than did the field-independent subjects. Also, the field-dependent subjects were found to be generally more dependent as people, to lack self-insight, to be more suggestible, and to have more inferiority feelings.

This work is an example of the approach to the understanding of individual personality through a study of individual perception. It is a particularly good example because it managed to avoid a major pitfall in this area: reliance on the subject's report to learn what he perceived. By using an objective physical manipulation, the adjustment of a rod to the vertical, it avoided the problem of determining whether the subject's report of his perceptions was an accurate one. A variety of motives besides the desire to report sensation accurately can influence what a subject says

he saw. Many experiments have indicated that people can be influenced in their own perceptual judgments by the judgments of others. For instance, a point of light in an otherwise pitch dark room will appear to move, probably because of natural eye movements. When a subject is asked to judge the distance of the excursion of the light and then is permitted to hear the judgments of others, his own subsequent judgment will be closer to the other judgments. The degree of modification will depend on an assortment of variables, including the consistency of others' judgments, the status of the other judges with respect to the subject, and the expertise attributed to the other judges.

In terms of the definition of perception, what is being manipulated here is, of course, the interpretation of sensory events by the individual. Since the light in the dark room does not in fact move, the sense data are somewhat ambiguous, and the subject is more prone to influence by social factors. Other experiments, however, indicate that, even with a more concrete sensory event, subjects are highly susceptible to suggestion in their reports of perceptual experience.

Learned Behavior

Much of perception is learned behavior. How much is actually learned and how much occurs as a result of the intrinsic organization of the nervous system is an issue that has occupied theorists ever since perception was first studied. Information pertaining to early perception is difficult to obtain because infants are not able to report what they see or hear. Some experiments on sensory deprivation, however, do yield information about what kinds of abilities are lacking when sensory experience is lacking. In a sensory deprivation experiment, the subject is removed from all stimulation possible. In experiments reported by Riesen, chimpanzees were raised wholly in the dark from birth until certain predetermined testing times. The chimps' vision was tested after varying periods of rearing in the dark; in this way, the importance of visual sensory experience in the development of visual perception was studied. Riesen found serious decrements in visual perception on the part of the chimps and also found that the length of time the animals were reared in the dark determined the possibility of reversing the decrements.

While such experimentation is not possible with human subjects, nature on occasion supplies relevant experimental conditions. Senden reports a series of studies of people who were blind from birth and who, at varying ages, underwent successful surgery for the removal of cataracts. Studies of their visual perception indicated that they had great difficulty in perceiving objects and even greater difficulty in distinguishing one object from another. Those who had learned to differentiate a square from a triangle by feeling the forms found that vision disrupted their recognition of the objects. What many became able to

do was to count the corners of the figures in order to distinguish them. Most of the younger subjects were able to acquire adequate visual perception with time and practice, but many of the older subjects sustained an apparently permanent visual handicap.

These experiments are interpreted by some as evidence of the importance of experience in the development of visual perception. But others point to the evidence that the timing and duration of sensory deprivation influence its effect on perception and argue for the possibility of innate or intrinsic factors in perception. Their argument is that perhaps certain abilities develop in the absence of stimulation at certain very early periods in life but do not develop after those critical times. However, recent research supports the position that learning and experience exercise very strong influences on perception. For instance, Krech, Rosenzweig, and Bennett report that perceptual discrimination ability can be enhanced by enriching the normal environment of rats.

Psychopathology and Perception

If the motivational and need states of the organism influence his perception of his environment, then it follows that psychopathological disturbance will have a profound effect on perceptual functioning.

Some experimentation in an area called "perceptual defense" makes this clear. A central experiment in this area was done by Postman, Bruner, and McGinnes. They found that words related to the highly valued areas of a subject's concern were recognized more quickly than were words related to areas of little or negative value to the subject. The term "perceptual defense" derives from the idea that the subject defended himself against the perception of words that had negative connotations for him; he took much longer to recognize them when they were presented. This was illustrated in another experiment by McGinnes in which he found that subjects took a longer time to recognize "taboo" words than neutral words.

An individual who has a pathological fear or need to avoid certain categories of people or experience may, therefore, be expected to "block out" perception of the threatening stimuli. It is possible that the mechanism by which this is done will ultimately be found in the neurophysiological processes by which Hernández-Peón's cat no longer perceived the clicks being presented when a mouse entered its visual field. It is also possible that future experimentation will reveal chemical changes in the brains of people with psychopathological disturbance and will reveal that these changes influence perception. It can be shown now that some drugs influence perceptual functioning and that different drugs influence it in different ways. Here the influence must be directly on the neural functioning underlying the apprehension and interpretation of stimuli. Some experimentation relevant to both the effects of drugs on perception and the effects of severe psychopathology on perception con-

cerns differential effects of the same drug on schizophrenics and on nonschizophrenic subjects.

Schizophrenics versus nonschizophrenics. The literature on the differences in perception between patients and normal subjects is voluminous, and much of it is contradictory. To review this field is a task far beyond the scope of this section, and no attempt will be made even to summarize it. A few examples should suffice to indicate the kinds of experiments and findings reported in the literature.

Whether one views serious mental illness as functional or in some measure organic, the perceptual studies relate to the influence of the perceiver and his needs and state on the content of the perception. Many of the studies have taken some objective behavior, such as reaction time, and studied its attributes in a patient population and in a nonpatient, and presumably normal, population. (In this way, schizophrenics especially have been compared with nonschizophrenic groups on a variety of perceptual measures—figure-ground differentiation, perceptual constancies, differential reaction times, and the like. It has been found, for example, that schizophrenics have a consistently and significantly slower reaction time than do nonschizophrenic subjects. However, attentional impairments can confound much research with schizophrenics: it may be that one is simply defining a difference in how much attention is being paid to the stimulus rather than a difference in the actual perception or speed of perception between schizophrenics and normal subjects.

Sutton and his colleagues, using a quite ingenious technique, avoided this problem of differential attention by first comparing the various aspects of the performance of a single individual and then comparing this relationship among parts to the same relationship obtained in the performance of nonschizophrenic subjects. Using this method, Sutton found that schizophrenics took relatively longer than normals to shift from one sensory modality to another. Since one of the prevalent clinical signs of schizophrenia is a kind of stickiness and perseveration, it is possible that this research is building a basis for objectifying and ultimately quantifying some clinical observations. This is an example of the way in which an attribute of perception can be used to study differences between groups of subjects and then to make hypotheses about the disease process.

Although much of the work in this area of perception and psychosis is done simply to define differences, at least one theory of psychopathology is used to predict the kinds of similarities and differences that might be found both between patient populations and normal ones and between the various groups and types of subjects within the patient population. Eysenck postulates a theory based on assumptions as to the state of the brain in various types of disturbances. For example, he says that a hypermanic individual has a cerebral cortex that is in a state of inhibition

and that a depressed individual's cortex is in a state of excitation. From this, Eysenck postulates that the hypermanic person will be much more difficult to condition than will the depressed individual. (Experiments done on these assumptions have yielded conflicting findings.) This is another example of how the perceptual processes have been used to reflect the properties of individuals.

This very brief discussion of the highly complex area of perception is meant to give a general orientation to the field and to its importance in the determination and the measurement of human behavior. Many important topics and areas have been omitted, and for a presentation of them, as well as for the fuller explication of those touched on here, the reader is referred to the bibliographic references.

Suggested Cross References

The clinical significance of disturbances in perception is discussed in Linn's chapter on psychiatric symptoms (Section 13.1) and also in Sands' section on the psychiatric examination (Section 11.2). Principles of perception are applied in the use of some of the psychological tests used in the assessment of psychiatric and neurological disorders. These are reviewed by Piotrowski in his discussion of projective tests (Section 12.1), and by Benton in his section on tests of organic brain damage (Section 12.2). Descriptions of specific disorders of perception, such as hallucinations and illusions, may be found in the sections dealing with the various psychiatric and neurological syndromes, especially the schizophrenic reactions (Chapter 15) and the organic brain disorders (Chapters 18 to 21), in Area F, on psychiatric disorders.

3.2 COGNITION

MARTIN DEUTSCH, Ph.D.

In his search for proof of his own existence, Descartes arrived at a satisfactory basis on which he could accept his own reality: "Cogito, ergo sum." "I think, therefore I am." This became a cornerstone of Cartesian philosophical doctrine, which has had a profound effect on modern science. What concerns us about Descartes' statement is that he affirmed his own existence in terms of the basic human process of thinking.

Cognition as a word is generally used to refer to more than thinking processes; for many theorists it includes sensation, perception, and learning processes. However, in contemporary usage, the main aspect of cognition is considered to be thinking and problem solving. Perhaps the very importance and inclusiveness of the area have made its margins somewhat fuzzy; exactly where cognition begins and perception or sensation ends, for example, is not entirely clear. For purposes of this section, however, we will discuss cognition mainly in terms of thinking and problem solving with only brief references to perception and learning.

First of all, cognition develops, and it develops in interaction with the circumstances of the individual's life. A number of theorists have defined stages in cognitive development. Most of these sets of stages have one particular progression in common: Cognitive development proceeds from the more concrete to the more abstract, from being more dependent on the actual presence and the sensing of stimuli in the environment to being relatively more independent of

concrete stimuli and operating, instead, with the symbolic representations of stimuli in memory. In essence, these progressions represent the change from having to manipulate objects in physical space to solve a problem to being able to manipulate the symbols of objects in one's mind in order to arrive at a solution. And here is where man emerges as the superior, symbolic animal, the one most capable of problem solving on the highest level.

When any part of man's symbolic language system is impaired, as by psychopathology in its many forms, his thinking or problem-solving process is adversely affected. Disturbed thought processes characterize most forms of mental illness. Through analysis of these thought processes, much insight can be gained into the nature of the individual's pathology and, by extrapolation from many such studies, into the nature of various types of disturbance.

Studies of thought processes and methods of problem solving in the nondisturbed individual also yield information that relates to personality organization and type. This is an area of study and theory called cognitive style. One aspect of individual differences is in their capacity to solve problems, sometimes referred to as intelligence. Although "intelligence" is one of those too encompassing words, one of its frequent definitions has to do with skill in problem solving.

From the discussion so far, it can be seen that what is referred to as "cognition" or "cognitive process" is a function related to problem solving, to symbolization, to the field of learning, and generally to a kind of aptitude called intelligence. Even this string of definitions and associations, however, does not quite explain the area referred to by the term "cognition." Perhaps an example used by William James provides the best description. In talking about the inception of cognitive life, James said that the point when it begins is when one is able to say, "Hello! Thingumbob again." In a sense, a discussion of cognition must revolve about the various skills and processes that make that exclamation possible. These would include recognition, recall, and symbolization (labeling). Implied in these skills is the development of the individual in interaction with his environment.

Language

Let us begin with language. In a sense, language may be considered the currency of cognition, at least for humans. We manipulate objects symbolically by labeling them. There is even a theory, proposed by Benjamin Whorf, that the structure of thought is determined by the structure of language. Essentially, such a theory means that, if there were a culture in which language did not include a past tense, it would be a culture without historical discussion. The Whorfian hypothesis has given considerable impetus to the study of semantics. Its enunciation has served in the behavioral sciences to place more emphasis on re-

search into linguistic processes and the acquisition of language by the child.

The Whorfian position represents an extreme point on the continuum of theories relating language to thought. A somewhat more moderate theory was suggested by Vygotsky, a Russian psychologist who studied both language acquisition and thought processes. His book *Thought and Language*, which was only recently translated into English, has considerably influenced this area of research and theory. Essentially, Vygotsky discusses thought as the progressive introjection of speech, and he regards thought and words as quite inseparable. He said: "The relation between thought and word is a living process; thought is born through words. A word devoid of thought is a dead thing, and a thought unembodied in words remains a shadow."

Verbal mediators. Many experiments have shown that adding language to apparently nonlinguistic problems facilitates their solution. For example, when labels are given to nonsense figures, it takes less time to learn their sequence.

Similarly, when prepositions are interjected between pairs of words that are to be learned, the number of repetitions needed to learn them decreases. For example, if the subject is to learn to say "table" after the experimenter says "hat," he learns the association faster if he adds, "on the" to himself; "hat on the table" is learned faster than simply "hat... table." This finding has been verified with many different groups of subjects, including those who are mentally retarded. According to some recent work of Jensen, the difference between retarded and normal subjects is that, if the normals are given the words to interpose on one occasion, they will make up such words on the next occasion; the retarded subjects, however, have to be supplied with the words each time. But for all of them, the use of interposed prepositions—called "verbal mediators"—speeds the learning of the word associations.

The field of verbal mediation in problem solving is receiving much attention at the present time. The assumption is that verbal mediators and labels play a very important role in the learning of even non-verbal material. For instance, learning to tell different bacteria apart is not essentially a verbal skill; it is a visual perceptual one. Yet, if one can label particular shapes verbally, it helps him remember and differentiate them.

This area of work has served to place much emphasis on the acquisition of language by children and on the study of their progressively greater familiarity and ease with it. It has stimulated a great many studies in language and the use of language. This work has implications for an understanding of cultural factors in thought and of linguistic factors in mental disturbance.

Acquisition of language. Language and its forms come to the child from his environment. He learns to speak the language of the people who surround him,

even though his *capacity* for language learning and use are a part of his biological endowment, anatomical and neurophysiological. It becomes apparent that, if language plays a major role in thought and if language is environmentally stimulated and its content environmentally determined, then environmental stimulation has much to do with thought.

As indicated earlier, Jensen found that all his groups of subjects for learning studies, except the mentally retarded, learned to supply their own mediators for remembering verbal stimuli. For some of these groups, however, he had to supply the mediators in the beginning; they did not supply their own mediators spontaneously. What, then, of the child who is reared in a largely nonverbal environment in which he neither spontaneously learns to use mediators nor is specifically taught to use them? Such a child may be perfectly capable of learning as fast as a more privileged child, but without the verbal facility he may be handicapped in the solution of many different types of problems.

Use of language

Social levels. That environmental and social factors play a large role in language usage is attested to by a number of investigators. Bernstein, in England, has done a substantial series of studies in this area and has concluded that social class designations—or, rather, the kinds of occupational, social, and environmental conditions that go along with certain social class levels—define also the type of verbal behavior seen in people.

Lower class families tend to show what Bernstein calls "restrictive speech codes," and middle class families tend to speak in what he designates as "elaborated codes." The two speech types differ from each other in the complexity of syntax, sentence length, richness of vocabulary, and several other categories used for linguistic analysis. What this means in everyday terms is that the lower class families have a less rich speech, and the middle class groups have a more complicated syntax and, therefore, a means for expressing more complicated thoughts.

The language of science, for example, is an elaborated code, but the language of the simple transaction in a store is a restricted code. This is not to say that children from lower class families who speak in restricted codes cannot become scientists; it is only to say that, according to this theory, they will have to develop a more elaborate language system, one that the middle class child is more likely to start school with in the first place.

Bernstein's results were obtained from studies he carried out in London, where the social class lines are much more rigidly drawn than in America. But investigators here have obtained data generally consistent with his findings. At the Institute for Developmental Studies in New York, investigators are discovering a more limited syntax for lower class children as com-

pared with middle class children. Hess and his associates in Chicago are reporting similar findings.

Child-rearing techniques. Hess's studies also attempted to relate language systems to child-rearing techniques, and here is another point of direct contact between language systems and personality organization. He found that the mothers who speak in restricted code are more likely to be what he calls "status-oriented" in their relationships with their children, but the mothers with the more elaborated speech codes tend to be what he defines as "person-oriented." The status-oriented mother, for example, disciplines her child in terms of "because I say so" and refers to the necessity for certain things to be done because "they say so" or because "the President says children should drink milk." On the other hand, the person-oriented mother is more likely to give reasons for actions and for discipline that are within the child's experience and his own motivations: "You should drink your milk because you want to grow up to be strong and healthy."

These differing kinds of child-rearing techniques can have very differing effects on the development of children's personalities. And these examples are only some of those available to illustrate the profound effect the variables labeled "cognitive" can have on personality development. These are not one-way effects; they are part of an interacting feedback, by which personality and emotional factors also influence cognition.

Language development. Many of the special programs designed to help disadvantaged children reflect the emphasis on linguistic influences in thought and the corresponding emphasis on social factors in language development. These programs are, in general, cognitive-enrichment efforts. They are directed toward the improvement of many cognitive skills, but a prime emphasis is language and language development. One of the reasons for the language enrichment is to improve the children's social communication skills; another reason is to influence their problem-solving abilities.

Irwin found substantial positive effects on children's language development simply from having their mothers read to them for half an hour every evening. Of course, when an adult reads to a child, there is usually a verbal interchange as well as the simple reading, so the effects are probably attributable to these other related language activities as well.

Development of Cognition

Many theorists define a series of stages in cognitive growth. Usually, these theories indicate that one stage grows out of the next and that the stages follow a certain invariable sequence. Most, but not all, of the theories include the supposition that each succeeding stage expands on and replaces the prior one, though there can be vestigial remnants of the previous stage.

Piaget's theories. A major theorist in this regard

is Jean Piaget, a Swiss psychologist, whose exhaustive and ingenious observations of his own three children provided the foundation for an entire elaborated developmental theory, with cognitive development at its base. For a long time in the United States the scientific *Zeitgeist* was such that the works of Piaget languished in libraries, with many of his books not even translated into English. This ignoring of Piaget stemmed from the American emphasis on emotional rather than cognitive development and the American stress on large sample, controlled experimental studies in preference to Piaget's naturalistic and small sample method. The growth of interest in cognitive development sparked a renewed interest in the work of Piaget, and a series of controlled experiments with children has verified some of the generalizations he made from his own observations. In turn, the theories and research stimulated by Piaget's work are coming to be regarded more and more as basically relevant to an understanding of the relationship between higher thought processes and emotional and social development and disability.

Schemata. During the entire developmental period, according to Piaget, the child is involved in building schemata, which are organizations of behaviors relevant to each other. Thus, there can be a "schema of sucking," which would include all the activities related to sucking: apprehension of the object to be sucked, activities of the mouth, lips, and hands during sucking, etc. The child's responses to the world are made up of schemata, though not exclusively. Piaget speaks more about schemata in the earlier, simpler cognitive periods than in the later periods.

Schemata are acquired by the dual processes of assimilation and accommodation. The first refers to the introjection of knowledge about the environment, which is then incorporated into the child's existing body of knowledge. In this incorporation, the existing body modifies somewhat to accommodate the new elements. It is by this continuing dual process that schemata are organized and changed, that concepts are built and expanded.

Stages of development. Piaget postulated a series of stages in cognitive development, beginning with what he designated the sensorimotor, progressing through the preoperational thought period to the stage of concrete operations into the period of formal operations. Age equivalents for these cognitive levels are very rough ones, with, presumably, fairly wide individual differences. A characteristic of the progression of levels is that the child becomes less and less dependent on particular external stimulation and more and more able to function in terms of symbols, without concrete referents.

In the first period, the sensorimotor stage, the infant begins as a reflexive organism that responds to its environment in an undifferentiated manner. Later in this stage he becomes an organism that displays, as Flavell put it, "a relatively coherent organization of

sensory-motor actions vis-a-vis his immediate environment."

The next stage, the preoperational thought period, is preparation for the stage that follows, the stage of concrete operations. In the preparatory stage, the child first begins to understand and use symbols, though he is able to do so only in unitary ways; double classifications elude him. For example, though he can understand that a particular person can be another child's mother—and, in fact, sees her in those terms: as "Johnny's mother" and not as "Mrs. Smith"—he is unable to see the same person in another classification as well: as "Mary's teacher."

By the end of the preoperational stage, the child is able to think in terms of classes, to see relationships, and to handle number concepts. He is still egocentric in his thought—he relates everything to himself, and his judgments are subjective—but the basis has been laid for the development of logical operations.

The stage of concrete operations includes the increasing ability to handle numbers, the development of a real logic, and an ability to relate external events to each other, independent of the self. The child can now classify the same person or object along more than one dimension. This period of from 7 to 11 years of age is one of massive intellectual and conceptual development. Interestingly, this period roughly corresponds to that defined in psychoanalysis as "latency": a period of relative overt quiescence in psychosexual development.

The last developmental stage that Piaget defined is the period of formal operations, from about 11 to about 15 years. This is when the child develops true abstract thought and is able to make hypotheses and test them logically. He has achieved conceptual independence from the concrete and can operate wholly with symbols, with no need to introduce the concrete objects they represent.

Within all these stages are many substages and the development of particular concepts and conceptual frames, such as concepts of time and size. Included in Piaget's system are accounts of the development of perceptual, linguistic, mathematical, and moral concepts. It is a developmental system, and it is an interactive one, in the sense that development is seen to take place as a function of the contact between the child and his environment. None of these functions is presumed to progress as described in the absence of environmental contact and interaction; the basic processes by which the development proceeds are accommodation and assimilation.

This point is emphasized, as it was in the discussion of language, because it contributes to a view of the individual as plastic in his development, and responsive to his surroundings. While the neural substrate must be responsible for the *possibility* for cognitive development to take place, it is the relationship between this neural substrate and the stimuli which act upon it which promotes the actual development. Such

an understanding occupies a central place in modern behavioral science: it offers the possibility of influencing man's development in the most basic sense. For fields which deal primarily in attempting to teach and to change people, such as psychiatry and education, it offers an optimistic view of potential success for both prevention and remediation of disability.

Stimulation and cognition

Intelligence. There has been a popular assumption that intelligence—which, in the context of this section, is the aptitude for cognitive development and cognitive functioning—is quite resistant to change by external intervention. The evidence does not bear out this assumption. There is, however, a consistency in scores on intelligence tests at age 8 and at adulthood in the absence of any special educational or interventional experiences in the interim. The consistency in intelligence test scores at age 2 and at age 8 is much less definitive.

The concept that intelligence is determined by the operation of internal processes, presumably genetically determined, is no longer current. Some theorists still hold to portions of it, but the evidence favors those who view intelligence as a function that develops in the relationships between the individual and his environment; that draws on various tools, such as language, which are developed in the same manner; and that grows or declines as a consequence of the amount and nature of environmental encounters. At the same time, these properties of change are relatively long term ones. Slight variations in living conditions, or very temporary ones, do not appreciably affect cognitive abilities.

Enrichment programs. Over the last 30 years, many programs have been mounted to attempt to enhance cognitive functioning. Many have been successful. Skeels, for example, found that the adoption of children from very poor and difficult institutional circumstances into more favorable ones enhanced their intelligence test scores substantially. In a follow-up study he reported maintenance of the positive changes associated with adoption. A control group of children, who were not adopted and who were studied at the same times, showed a maintenance, on the whole, of the lower functional levels.

Wellman reported positive changes in intellectual functioning as a result of a special nursery school experience. More recently, Kirk reported significant improvement of cognitive skills of mentally retarded youngsters enrolled in a special preschool program. Although the improvement did not continue after the end of the special program, the gains acquired were not lost.

Current attempts to enhance cognitive development with special programs are also focused on the preschool years. The long term programs that begin for 4-year-olds and continue for several years are as yet too new to show definitive long term results, but the

short term gains they report are significant in terms of raising functional cognitive levels and intelligence test scores.

On the basis of these results, large scale short term programs are being mounted all over the country with support granted under the antipoverty legislation. This is just one example of how both theory and research from the behavioral science field are applied to current social problems. This application, in turn, can be expected to stimulate more research and experimental programs in the cognitive area.

Reading. The general ferment about stimulation of cognitive processes has also affected thinking about the skill of reading. For many years, the educational dogma stated that teaching children to read too early could be harmful to them and that the appropriate age to learn reading was approximately 6. This emphasis on the potentially harmful effects of earlier teaching effectively stopped experimentation with reading at earlier ages, even though Davidson in 1931 was able to make substantial progress in teaching reading to children who had a mental age of 4, including some retarded 5-year-old children.

Now interest in early reading has been reawakened, and many educators are rethinking their earlier opposition. As with other cognitive skills, there are vast individual differences in the ages at which children can acquire reading skill, but there is no scientific basis to any assertion of inevitable harmful effects from early teaching. Not all children are able to learn before 6, but apparently the only harm that comes from earlier attempts to teach them is caused by coercive methods used, rather than by such attempts per se.

Effects of environment. There is evidence that, in the absence of special intervention, children in a non-stimulating environment will show a drop in intelligence test scores over years. This was reported in 1924 by Gordon, who studied gypsy children in Europe whose schooling and cognitive stimulation was highly irregular because the families lived on traveling barges. Gray and Klaus refer to this phenomenon as "progressive retardation," and Deutsch and Brown call it "cumulative deficit."

The influence of environment on intelligence can also be positive, even in the absence of specific programs of stimulation. Klineberg did a classic study that showed significant intelligence test score increases for Negro children who moved from poor and unstimulating environments in the South to better living conditions and better school situations in the North.

Personality and Cognition

Interrelationships among cognitive processes affect the individual's intercorrelated modes of thinking, problem solving, and perceiving, which in current literature are referred to as "cognitive style." Kagan and his associates studied the development of such styles in children and defined certain consistencies over time. They also found relationships between the styles

of analyzers and nonanalyzers and their motoric impulsivity, with the nonanalyzers being much more impulsive and generally motoric in their reactions.

The authoritarian personality. A book by Adorno and his associates, *The Authoritarian Personality*, represents one of the first systematic attempts to relate certain personality characteristics, attitudes, and cognitive orientation. The studies reported in that book and elsewhere were oriented toward the personality and cognitive correlates of particular political attitudes, but part of the approach involved study of the relationships among perception, cognition, and personality. In general, those studies report a correspondence among fascist political attitudes, a status-oriented view of interpersonal relationships, and a cognitive rigidity.

This series of studies has been criticized because of the involvement with the definition of an authoritarian personality—although that was the aim of the studies in the first place—and the correspondingly lighter emphasis on definitions of other personality types and their cognitive correlates. However, the authoritarian personality studies set the pace in this area and provided an impetus for work that is still being felt. In the criticism and discussion of the book, many theories were formulated, and many investigators were stimulated to carry out related work.

Some interpretations of the data contained in the authoritarian personality studies have quite direct relevance to the process by which individuals can be influenced to alter their behavioral modes. For instance, Brown suggested that the person with the authoritarian mind can be classified in terms of the kinds of information that will influence him to alter his thinking about particular topics. Brown said that the more the authoritarian an individual's orientation is, the more he can be induced to change his mind because of the statements of authority or high status figures alone. As the individual approaches the nonauthoritarian point on the continuum, the more he will need other kinds of evidence to change his thought or attitude.

The open and closed mind. Following in the tradition of the authoritarian personality studies, but avoiding many of the pioneering pitfalls, Rokeach reported a series of studies in a book entitled *The Open and Closed Mind*. According to his studies, the closed mind person is dogmatic and rigid and is characterized by the operation of many mechanisms of defense, which serve to shield him from uncomfortable conflicts in his belief systems. The open mind, on the other hand, is just that: open to external stimuli and more apt to be probing the world of knowledge, seeking more information.

Almost the same type of dichotomy was enunciated by Witkin and his associates under the "field-dependent" versus "field-independent" rubric. Goldstein and Scheerer, in work that antedated the authoritarian personality studies, and that was oriented less to attitudes and more to "pure" cognitive abilities, which

they related to the presence or absence of central nervous system disability, defined two groups as "concrete" thinkers and "abstract" thinkers. Many other investigators have come to similar conclusions, albeit in different words.

Allport summed up the individual characteristics defined by all these investigators: "Some people are chronically unable to change their sets when objective conditions demand it; others, by contrast, are flexible."

What is most relevant about this work to the general field of psychiatry is its union of the cognitive and the emotional—the relationship defined among belief systems, cognitive rigidities, and personality orientations. This is perhaps best enunciated by Rokeach in *The Open and Closed Mind*:

Many important aspects of intellectual functioning in particular and cognitive functioning in general can be attributed to personality rather than to intelligence.... It is possible to investigate many spheres of activity—ideological, conceptual, perceptual, and esthetic—via the common structural bond that ties them all together in the person's belief system.... A person's cognitive functioning is not a thing apart from his affective or emotional functioning. They are seen to be different facets of a person's total behavior.

Kagan, Shaffer, and Frenkel-Brunswik all indicated that these systems or styles develop early and are influenced by child-rearing practices.

Psychopathology and Cognition

The relationship between development and cognitive style and between the cognitive and the emotional has provided the basis for extensive inquiry into the thought processes of persons who are emotionally disturbed.

Comparisons with children and primitives. One of the most specific discussions of the relationship between development of cognitive skills in children and their dissolution in the mentally disturbed is in Werner's book, *Comparative Psychology of Mental Development*. The book presents a system of mental development that includes stages not too different from those enunciated by Piaget. Werner, however, is concerned with the entire life span and is more concerned than Piaget with brain function. Werner propounds a complex theory of mental development and cognition that includes comparisons among cultures, among individuals at different points in the life span, and among individuals with different types of organic and psychological pathology.

The fact that children, individuals with brain damage, and those with various forms of psychopathology are all concrete in their thought processes has tempted many theorists to compare these clinical groups to children. Cross-cultural studies, too, at times relate primitive concrete thought to the concretism found in children in our culture. Werner labeled all these comparisons false and disposed of them by pointing out that there is an essential difference between the concretism of the developing child and the regression to

concretism that characterizes the disturbed or organically impaired adult. With regard to equating the primitive thought of psychopathology with primitive thought in primitive cultures, he said, "The primitive man lives in a world to which he is admirably adjusted; the pathological individual tries to adjust himself by means of primitive behavior to a world for him inadequate and nonprimitive." He also pointed out that any developmental stage contains elements of the preceding one and, therefore, that the primitive and concrete thought of the mentally ill adult contains vestiges of his earlier, more abstract, and intact functioning.

Schizophrenic cognition. There is voluminous literature on thought processes in mental disease. About the only common point of departure for most researchers in this area has been the conviction that schizophrenic thought is somehow different from normal thought.

Investigators in this area have operated from different theories of cognition and from varying theories and definitions of mental illness. The experimental results are inconclusive and often contradictory. The reliability of these results is further confounded by the widespread experimental use of either heterogeneous schizophrenic populations or differently classified populations. The classical diagnostic categories of hebephrenic or paranoid schizophrenia have been used, as have newer categories, such as process-reactive, chronic-acute, and good and poor premorbid schizophrenics. Also, schizophrenic cognition or conceptual ability has been measured by a wide variety of tests, ranging from I.Q. and simple learning tests to "higher order" tests of concept formation and deductive, inductive, and abstract reasoning.

Conceptual ability. Experiments concerning schizophrenic conceptual ability have yielded results that range from no conceptual deficit in schizophrenia to specific deficits associated with the type of psychosis to significant differences between *all* schizophrenic and normal subjects. Although the issue is still controversial, recent research has indicated that schizophrenics are not necessarily unable to form concepts and that the concepts they form are not significantly concrete or infantile. Rather, it has been pointed out that schizophrenics may be concerned with bizarre and personal concepts that they are unwilling to communicate or that they communicate in a private language. Other theorists have demonstrated that schizophrenic concept formation ability can be raised to a normal level by decreasing the number of distracting stimuli and that their conceptual performance can be significantly lowered by increasing the number of stimulus distractions.

Conceptual functioning. Schizophrenics have often been observed to include irrelevant and extraneous factors in their response to a conceptual task, a phenomenon termed "overinclusion." Such a phenomenon has been explained on the basis of a schizophrenic inability to select only those stimuli that are relevant to

the task being performed. The results in this area are controversial and are not easily fitted into a single or simple theoretical framework. But the results may be summarized in the following way. Although some schizophrenics may form bizarre or personal concepts and may exhibit the phenomenon of overinclusive thinking, all schizophrenics, including the chronic population, have performed normally on a variety of conceptual tasks when time pressure and distractions were eliminated and when the levels of stimulus input (cue information) and motivation were increased.

Several major theoretical approaches have attempted to account for schizophrenic conceptual performance. One theory, presented by Goldstein and Scheerer in 1941, characterized schizophrenic thought as concrete; schizophrenics, like brain-damaged patients, are seen as having lost the ability to think in the abstract. Although early results with the Goldstein-Scheerer and Vygotsky blocks tests tended to support this view, research in the last decade has generally tended to disprove it.

Another theory was presented more recently by Arieti, who characterized schizophrenic thought as paralogical, dreamlike, and primitive rather than logical. He suggested that the schizophrenic is unable to handle stress and, therefore, regresses to a less advanced level of personality integration. The schizophrenic then uses his thought processes to isolate himself from a threatening social environment. This withdrawal or desocialization takes place together with, or even because of, a concomitant process of cognitive desymbolization. In this state, objects assume a different and highly personal meaning to the schizophrenic.

Williams attempted what he regarded as a test of Arieti's theory, but the tasks he used did not yield differences in logical and syllogistic reasoning between schizophrenics and normals. This should by no means be considered a definitive disconfirmation of Arieti's theory, as the tasks Williams used may not have been adequately reflective of the kinds of logical difficulties that schizophrenics have. It is also possible that the testing situation influenced the performance of the subjects. There is some evidence, for example, that the conditions set for task performance influence the functioning of schizophrenics in predictable ways. This would mean that at least some persons with schizophrenia are still related enough to the world around them to be influenced by it, at least in cognitive functions.

A number of theorists have suggested that the apparent cognitive deficit observed in schizophrenia is a function of a high anxiety level, impaired attentional and time reaction abilities, a lowered motivation level, and an oversensitivity to distractions. Some experiments in the area have tended to support these theories.

It is becoming fairly clear that the cognitive styles in schizophrenia are not necessarily stable and irreversible ones. Experiments have demonstrated that the abstracting and interpreting ability of mildly disturbed

schizophrenics can be improved under conditions of enriched stimulus information. Schizophrenic concept formation ability can be significantly improved and raised to normal levels under avoidance learning conditions, by presenting subjects with a noxious stimulus that can be terminated by the correct conceptual response. In general, these results tend to support other experiments concerning less complex cognitive and learning tasks in which the schizophrenic response improved under conditions of punishment, censure, or failure threat.

The relationship of schizophrenic functioning to the nature of the task presented is supported by evidence, reported by Hunt and Cofer, that the schizophrenic functional deficit becomes greater as the complexity of the task increases. Mednick used this concept to reconcile the differing views of various investigators with respect to the thinking disorder seen in schizophrenia. He pointed out that "thinking is perhaps the most complex behavior in which man can engage" and indicated, therefore, that this would be a focus for schizophrenic dysfunction. Although theorists differ, Mednick believes that they all acknowledge that the thought of the schizophrenic can be described as disordered and that this disorganization results from irrelevant, fragmented, and competing associations.

One view of the genesis of such disorder is that it represents a reaction to stress. This assumption underlies one view of delusions, a prominent characteristic of certain types of schizophrenia. McReynolds, for example, said that a delusion may be viewed as a form of cognitive reorganization that desensitizes threatening and anxiety-producing thoughts by reinterpreting them. Thus, a delusion should be a less threatening organization of information for the schizophrenic. McReynolds and his associates later made a somewhat oblique test of his view of a delusion and confirmed his earlier theorizing. No experiment should be regarded as definitive, but this one does represent a promising line of investigation of cognitive functioning and cognitive deficits in schizophrenics.

Memory

Memory is an integral part of all thinking and learning, but it has also been studied separately in a variety of ways. First of all, it is well known that memory plays tricks—in the sense that one does not always remember accurately what one learned or experienced—and that these inaccuracies are, in part, a function of individual experience. Different individuals in the same situation will later remember different aspects of it and are likely to remember the same aspects differently. A portion of these differences can be attributed to their differential apprehension of the experience in the first place. But another portion can be related to vagaries of memory function and to the influence of the individuals' varied experiences subsequent to the experience which is being recalled.

Intervening experiences. Experimental studies of

memory indicate that what is remembered is related to the experience that intervenes between the initial learning and the recall. The closer the intervening experience is to the learning situation, the more interference there is with the initial learning and, therefore, the more data is lost in the recall or is confused with the subsequent learning. For example, if one were to learn the names of all the rivers in Africa and then learn the life cycle of the snail, the chances are that he would do better on a subsequent test of his knowledge of African rivers than if that learning had been followed by the learning of the names of African mountains.

Testing methods. Accuracy of memory varies also with the method used to test it. The most difficult circumstance in which to remember something is in response to an open-ended question that gives no information itself; for instance, "Name the rivers of Africa." If one were asked to name four rivers in Africa that begin with the letter "N," the task would be somewhat easier. The simplest form of the task would be to pick out the African rivers from a list that includes rivers of other continents.

Timing. There are also differences between immediate memory and memory for events that occurred longer ago. The memory defect in senility is so well defined, in fact, that it is used diagnostically; the senile person has a much better memory for remote events than for recent events.

Drugs. Certain drugs apparently enhance or interfere with memory functions. Scopolamine, for example, seems to cause forgetfulness, and some of the hallucinogens, such as lysergic acid diethylamide (LSD), seem to heighten both sensation and memory. The effects of drugs on memory and on other cognitive functions provide a promising line of investigation into the nature of the cognitive process and its deficit in various forms of psychopathology.

Summary

Cognition includes many points of relationship between cognitive and emotional processes and their subsequent interaction and relationship with that individual orientational entity called personality. However, relationship does not imply causation. From the data reported and discussed, it is not possible to say that cognitive processes *cause* particular emotional reactions or that those reactions *cause* particular cognitive perceptions or distortions. Rather, the functions are related and interrelated, and all owe their genesis, in one degree or another, to the relating of the individual to his environmental and social circumstances. Vygotsky said with respect to language, "Words play a central part not only in the development of thought but in the historical growth of consciousness as a whole. A word is a microcosm of human consciousness." The same could be claimed for each of the elements discussed here.

Suggested Cross References

The neurophysiological basis of memory is discussed by John in Section 2.10. For some clinical applications of the concepts of cognition see Piotrowski's section on psychological tests (Section 12.1), with special reference to tests of intellectual functioning, and Benton's section on tests for organic brain damage (Section 12.2). Sands also discusses the assessment of disturbed cognitive functions in Section 11.2, on the psychiatric examination. Linn's section on signs and symptoms of psychiatric disorders (Section 13.1) contains descriptions of the various forms of thinking disorders seen in the clinical practice of psychiatry. Finally, a more detailed account of the specific disorders mentioned in this section, such as schizophrenia, organic brain syndromes, and mental retardation, may be found in Area F.

3.3 LEARNING

ARTHUR J. BACHRACH, Ph.D.

Learning is basic to every form of psychological theory. As Hilgard observed, "Psychologists with a penchant for systems find a theory of learning essential because so much of man's diverse behavior is the result of learning. If the rich diversity of behavior is to be understood in accordance with a few principles, it is evident that some of these principles will have to do with the way in which learning comes about." When Hilgard asserted that learning theory is critical "if the rich diversity of behavior is to be understood in accordance with a few principles," he was stating an assumption completely in keeping with a scientific method designed for explanations of events in terms of lawfulness and a striving for a minimal set of rational, demonstrable principles to account for these events. In a laboratory science such as experimental psychology, the search for laws of learning has been carried on with just such methods. The leaders in formulating theories of learning—Hull, Tolman, Skinner, Spence, Thorndike, Pavlov, and Guthrie—have all been, to one degree or another, laboratory scientists committed to research. A major part of their efforts and those of their colleagues has been the definition of learning variables.

The definition of learning has always been a difficult problem. Kimble has suggested that the roads to definition are two—factual and theoretical. The factual definitions relate learning to observable events in the physical world. The theoretical definitions are concerned with descriptions of basic processes that the learning theorist believes to be necessary in order for learning to occur. Hebb illustrated the theoretical defi-

nition when he discussed central nervous system (CNS) activities, the neural messages that occur in the CNS pathways: "Learning means a change in the direction of messages in the CNS." Skinner, in discussing response probability as a basic datum in the learning process, offered a factual definition: "We may define learning as a change in the probability of response, but we must also specify the conditions under which it comes about." Hebb was postulating changes in the CNS that may be difficult to observe. Skinner concentrated on the frequency and altered probability of a specific observable response under specified observable conditions.

There is, withal, a general agreement that somehow learning is a change in behavior that results from practice, with learning representing an intervening process or variable which links organismic states before and after a change in behavior occurs. As Kimble observed, the definition of learning always assumes a relatively permanent change in behavior, excluding changes resulting from maturation, sensory adaptation, or fatigue.

The central question has always been one of differentiating learning from performance. Learning is inferred from observed performance. Kimble saw learning as a change in behavior potentiality. The organism may acquire capabilities to perform some act through learning, but the act itself may not occur. He stated, "Learning refers to long-term changes of the organism produced by practice... Performance... refers [to the] translation of learning into behavior." At this point Kimble introduced another aspect of the definition in observing that practice alone does not produce learning; it is necessary for some maintaining event to occur, and so it is necessary to add reinforcement. Sidman defined reinforcement as "any event, contingent upon the response of the organism that alters the future likelihood of that response."

Learning, then, is defined as a change in behavior potential resulting from reinforced practice. Reinforcement, as so considered, becomes an example of an empirical law of effect that is basic to much of contemporary learning theory. The law of effect, as stated by Thorndike in 1931 says: "Acts followed by a state of affairs which the individual does not avoid, and which he often tries to preserve or attain, are selected and fixated, while acts followed by states of affairs which the individual avoids or attempts to change are eliminated." The following year, 1932, Thorndike modified his law and indicated that rewarded responses were always strengthened but that punished responses did not always diminish in strength, thus leading to an emphasis on reward as a primary determiner of behavior.

Conditioning

(It is fairly traditional to view conditioning as a case of learning.) Hull in many of his writings described the classical Pavlovian conditioned reflex as a

special case of the law of effect, assuming reinforcement to be operative in such simple learning examples as well as in higher order learning. Most theorists accept a rough dichotomy between two types of conditioning: classical (Pavlovian) and instrumental conditioning.

Classical conditioning. Ivan Pavlov, the Russian physiologist, observed in his work with gastric secretions in dogs that stimuli that were often present at the time the dogs were offered food came to evoke salivation in the animals even in the absence of food. For example, the footsteps of the experimenter as he entered the room came to evoke salivation in dogs, even though the dogs could not see or smell food. Pavlov assumed that the stimulus of the footsteps came to be associated with food. His research was directed toward an analysis of this event, which he called the "conditional reflex" (the reflex would occur, given certain conditions), later somewhat mis-translated as the more familiar "conditioned reflex" or "conditioned response."

In a typical Pavlovian experiment, a stimulus that, prior to training, had no capacity to evoke a particular type of response becomes able to do so. To illustrate: under normal circumstances, a bell sounded near an animal will probably do no more than evoke exploration, such as a turning of the head toward the sound or perhaps, at most, a startle response. Also, under normal circumstances, a hungry animal may be expected to salivate in the presence of food. Pavlov's conditioned reflex experiment was a training experience in which the previously neutral stimulus of a bell was made (by pairing it with the food) to evoke the response of salivation, which it normally would not do.

To diagram this:

Preconditioning: $S \longrightarrow R$
 (bell) (exploration)

$S \longrightarrow R$
 (food) (salivation)

Conditioning: $S(\text{bell}) \longrightarrow S(\text{food}) \longrightarrow R(\text{salivation})$

Bell sounds are followed by the presentation of food. The animal salivates at the sight of the food and ultimately pairs S (bell) and S (food).

Postconditioning: $S(\text{bell}) \longrightarrow R(\text{exploration})$

'conditioned
 ↓
 $S(\text{food}) \longrightarrow R(\text{salivation})$
 (unconditioned stimulus) (unconditioned response)

Because the food naturally produces salivation, it is referred to as an unconditioned stimulus. Because the bell was originally unable to evoke salivation but, by pairing with the food, came to do so, it is referred to as a conditioned stimulus.

Instrumental conditioning. In contrast to classical conditioning, in which the organism is usually restrained (in a Pavlovian harness, for example) and in which the response is elicited by the experimenter, instrumental conditioning is an experimental technique in which a freely moving organism emits behavior that is instrumental in producing a reward. For instance, a cat in a Thorndike puzzle box must learn to lift a latch in order to escape from the box; a monkey in an experimental chair must press a lever to effect the presentation of food.

Sanford lists four kinds of instrumental conditioning:

The simplest kind is called *primary reward conditioning*. The learned response is instrumental in obtaining a biologically significant reward, such as a pellet of food or a drink of water. In *escape conditioning* the organism learns a response that is instrumental in getting him out of some place he prefers not to be. *Avoidance conditioning* is the kind of learning in which a response to a cue is instrumental in avoiding a painful experience. A rat on a grid, for example, may avoid a shock if he quickly pushes a lever when a light signal goes on. *Secondary reward conditioning* is that in which there is instrumental behavior to get at a stimulus which has no biological utility itself but which has in the past been associated with a biologically significant stimulus. For example, chimpanzees will learn to press a lever to obtain poker chips, which they insert in a slot to secure grapes. Later they will work to accumulate poker chips even when they are not interested in grapes.

Generally, it is assumed that most learning occurs as a result of instrumental responding, rather than as an elicited consequence of classical conditioning. But both classical and instrumental conditioning techniques have begun to occupy a central place in the theoretical and practical behaviors of a growing group of clinicians who consider their methods to be clearly based upon experimental laboratory procedures, therapists who derive their techniques and principles from learning theory as based in the laboratory. The clinicians—represented by such theorists as Mowrer, Wolpe, and the followers of methods developed by Skinner—refer to themselves as "behavior therapists," "learning therapists," and "conditioning therapists," such appellations being virtually interchangeable and synonymous.

The most influential contemporary theories of learning have been advanced by Hull (upon whose theoretical structure much of Wolpe's work is based) and Skinner (whose methods are basic to operant conditioning techniques in treatment). These theorists fall within the group of learning theorists espousing a reinforcement model of learning. The two-factor learning theory espoused by Mowrer, in which classical conditioning and reinforcement theory are considered, has also been influential.

Hull's Learning Theory

Clark Hull's approach to learning theory is strongly mathematical and neurophysiological. He sought to establish a theory of behavior (which he equated with

learning) that could be quantified and tested in accordance with scientific method. In his book *Principles of Behavior*, Hull described the learning process this way: "Just as the inherited equipment of reaction tendencies consists of receptor-effector connections, so the process of learning consists in the strengthening of certain of these connections as contrasted with others, or in the setting up of quite new connections." For Hull, these connections occurred internally and were mediated by nervous system stimulation. The establishment of a connection occurred as follows:

$$S \rightarrow s \rightarrow r \rightarrow R$$

where an external stimulus, S , has as its function the stimulation of an efferent system, s , which, in turn, effects a motor impulse, r , within the nervous system. The final response, external R , does not have to occur for learning to take place: the critical connection is the s - r connection, leading to a "habit."

Habit family hierarchy. The habit, for Hull, is an established connection within the nervous system, but these connections are not limited. The concept of the habit family hierarchy allows for transfer of learning or generalization to occur. Thus, a given stimulus, S , may evoke a number of different responses in varying levels of strength, but this stimulus, as we have noted, evokes a response or set of responses within the nervous system that anticipate a goal response. For Hull, the goal response is antedated by fractional responses in the establishment of a habit. Thus, r may become a fractional response, an element of R , called a "fractional anticipatory goal response" or r_G , which in itself is stimulating. "A fractional anticipatory goal reaction must," said Hull, "produce continuously a stimulation (s_G) characteristic of the point of reinforcement or goal situation... s_G becomes a guiding stimulus leading to its own realization, to the final complete act of which it is a part. As such, the fractional goal reaction (r_G) is a *pure stimulus act*, i.e., an act whose only biological or survival function is that of producing a stimulus for the control of other action of a more direct adaptive value." The fractional response, r_G , then becomes a mediating element between S and R . An example of this is salivation occurring before the consummatory goal response of eating.

Because there is variability in response sequences leading to a goal as a result of varying environmental conditions, Hull postulated that "since all the alternative behavior sequences have led to the same goal, all of the component acts of all the sequences will alike be conditioned to the same fractional anticipatory goal-reaction stimulus (s_G), and in this sense will constitute a *family*."

The habit family hierarchy, noted Bugelski, proposes that "any of a number of S 's can eventuate in the same R_G goal response." There is a common fractional goal reaction (r_G) to all the elements in the series, and hence in the habit family, but some of

these will be weaker than others in excitatory potential (Hull suggested that this results from being more remote from the final R_G at the beginning of the sequence); therefore, they form a hierarchy of strength. This conceptualization forms an important basis for the therapeutic application of this learning theory, inasmuch as it allows for an analysis of behavior clearly in terms of adaptation through alternative response conditioning.

Hull's concept of drive. Thorndike's law of effect used the concept of satisfaction to account for reinforcing effects of certain responses. Hull attempted to make the satisfying element less subjective by stating the law of effect as he understood it to be: "If the central afferent receptor discharge (s_c) of a stimulus element (S_c) of a stimulus compound is active in the central nervous system at the same time that a reaction (r_u) is evoked and if at about this time there occurs a 'reinforcing state of affairs,' there will result from this conjunction of events an increment to a habit (s_Hr). The "reinforcing state of affairs," for Hull, represented the "diminution in a need (and the associated diminution in the drive (D))."

This principle of primary reinforcement is clearly a drive reduction approach: attaining the goal response reduces the drive associated with the aroused need, strengthening the behaviors that led to the reduction in tension. This strengthened sequence becomes the habit.

Inhibition. Hull postulated that neural impulses (afferent receptor discharges) "occurring at about the same time interact and so modify each other." He called this afferent interaction and viewed this as a basis for the reduction or elimination of a response through the presence of an "extra or alien stimulus in a conditioned stimulus compound which can reduce the excitatory potential." An example of this is the interference of "irrelevant stimulations resulting from an emotional upset" that may disrupt a child's classroom performance.

Hull saw this as equivalent to Pavlov's external inhibition. Pavlov's concept of internal inhibition is similar to Hull's conditioned inhibition (s_I), which resulted from reactive inhibition, a "negative drive state" similar to fatigue or physiological impairment resulting from activity. Hull's conditioned inhibition is an interfering set of events.

This brief summary of salient features of Hullian learning theory indicates that Hull's theoretical position was largely based on neurophysiological postulates and concerned itself with drive and drive reduction as basic to reinforcement. Let us turn now to Wolpe's behavior therapy and briefly examine its Hullian bases.

Wolpe's Conditioning Theory

Wolpe defined neurotic behavior as behavior that "consists of persistent habits of learned (conditioned) unadaptive behavior acquired in anxiety-generating

situations." It is no coincidence that Wolpe invokes the term "habit" to describe neurotic behavior in this regard. The Hullian influence becomes clear again in the following observation about anxiety responses: "They necessarily produce anxiety drive (with concomitant central neural excitation) as an antecedent." He also reflects this neural approach to learning when he notes that "learning is subserved by the development of conductivity between neurons in anatomical apposition." Here we see the Hullian concepts of learning as being mediated by central nervous system activity, the neurophysiological basis of drive, and anxiety as a drive leading, presumably, to activity aimed at drive reduction.

Reciprocal inhibition. Wolpe also reflected a Hullian orientation in his important principle of reciprocal inhibition, which may account for anxiety drive reduction: "If a response inhibitory to anxiety can be made to occur in the presence of anxiety-evoking stimuli, it will weaken the connection between these stimuli and the anxiety responses." Relaxation, for example, is considered to be incompatible with and, therefore, inhibitory to anxiety.

Anxiety hierarchy. Wolpe also used Hull's concept of habit family hierarchy in an interesting clinical fashion when he established anxiety hierarchy relationships among anxiety-evoking stimuli. Assuming that varying stimuli may evoke the response of anxiety, Wolpe asks his patient to imagine (usually under hypnosis) the least disturbing item of a list of potential anxiety-evoking stimuli, then to proceed up the list to the most disturbing stimuli. For example, a patient with a fear of death might rank the sight of a coffin lower in the hierarchy than a corpse (highest intensity), with perhaps a tombstone ranked somewhere in between.

Wolpe's technique of desensitization is a counter-conditioning technique in which responses designed to inhibit the anxiety response are evoked at each level along the hierarchy. Reciprocal inhibition of the fear response is thus conditioned.

Skinner's Learning Theory: Operant Conditioning

Proponents of an experimental analysis of behavior based on operant conditioning techniques and also reinforcement theorists form a group of behaviorists who tend largely to minimize theoretical considerations and to concentrate on an analysis of the functional relationships among events. For example, instead of dealing with the repression of unacceptable thoughts, as psychoanalysts do, Skinner suggested that it is more important to avoid the inner causes and to emphasize the questions that ask "why the response was emitted in the first place, why it was punished, and what current variables are active."

The term operant refers to a class of responses that are emitted by the organism rather than elicited by some known stimulus. Operant responses are also fre-

quently referred to by such terms as "voluntary," as opposed to "involuntary" or reflex behavior. Reflex responses are elicited, as in classical conditioning, and are termed respondents. Thus respondents, such as pupillary reflexes, are differentiated from operants. An example of an operant response is reaching for a telephone. An operant has some effect on the environment. Keller observes: "Respondents, right from the start, are evoked by their own special stimuli. Food in the mouth will bring salivation. . . . In the case of operants, however, there are at the beginning no specific stimuli with which we can evoke them. Rather, we are compelled to wait until they appear before we can do anything about them. . . . It is for this reason we may speak of operant behavior as emitted ('sent out') rather than elicited."

Skinner in his first major work, *The Behavior of Organisms*, differentiated two types of conditioning, which he called type S and type R. Type S conditioning "is defined by the operation of the simultaneous presentation of the reinforcing stimulus and another stimulus." In type R conditioning, the reinforcing stimulus "is contingent upon a response." This distinction between classical (respondent, involuntary, type S) and instrumental (operant, voluntary, type R) conditioning is not entirely accepted by many learning theorists, on the grounds that the criteria are too ambiguous. Psychophysiological interactions, for example, are not clearly differentiated into operant or respondent. For most purposes, however, the distinction can be a useful one if one avoids the tendency to let theoretical niceties restructure the nervous system.

Reinforcement. A key concept in operant conditioning is that of reinforcement, which, as was noted earlier, Sidman defined as "any event, contingent upon the response of the organism that alters the future likelihood of that response." In operant conditioning the term positive reinforcement is used to describe an event consequent upon a response that increases the probability of that response recurring. A negative reinforcement is an event likely to decrease the probability of that response's recurrence. A negative reinforcement is an event that strengthens the response that removes it; for example, if a punishing consequence attaches to a response, any behavior that avoids or escapes the punishment will be strengthened, that is, increased in probability.

Response frequency. Another important concept is the use of response frequency as a basic datum. The frequency with which a response is emitted is a clear, observable measure of behavior. Skinner has observed that personality descriptions are couched in frequency terms; to say that a person is "an enthusiastic skier," "an inveterate gambler," or "hostile" reduces to a statement of a perceived frequency with which a certain class of behavior is emitted, presumably with some normative conceptualization in mind. "Aggressive" behavior is emitted by most people; to say that a person is "hostile" suggests that this class

of response occurs with a higher level of frequency than is usually expected.

Shaping behavior. The concept of shaping is also of importance in discussing operant conditioning. Working with a freely moving organism, the experimenter selects the final response he desires to produce. Sidman describes the shaping process this way:

Shaping is accomplished by reinforcing successively closer approximations to the behavior with which the experimenter ultimately wants to work. The experimental situation, for example, may be one in which a monkey is to be reinforced with food for pressing a lever. If the monkey just sits quietly at first, the experimenter will wait until the animal moves and will then immediately deliver the food. By continuing to reinforce all movements, the experimenter will soon have an active animal with which to work. He then reinforces only those responses which bring the animal closer to the lever, as if drawn by an invisible string. The experimenter now directs his attention to the animal's hand. He delivers the food whenever the hand moves closer to the lever, and it is not long before the animal places its hand on the lever and depresses it. The experimenter can then turn the rest of the job over to his automatic apparatus, which will deliver the food only when the animal actually depresses the lever.

This successive approximation, by steps, towards the final terminal behavior is a critical aspect of the experimental method. But it is necessary to specify the response desired, not in general terms but by specific behavioral criteria. One of the key factors in operant conditioning is the frequency with which a carefully specified response occurs in an equally carefully defined environment.

Control of the environment does not necessarily mean the rigorous controls of an experimental laboratory. Skinner, in a paper on teaching animals, observed that it takes a controlled laboratory situation to work out full learning experiments but that a great deal can be accomplished under informal home conditions, provided that the elements of reinforcement (such as food for the family dog) and a conditioned reinforcer (such as a snap cricket) are present.

Operant paradigm. A summary statement of basic concepts in operant conditioning has been presented by Goldiamond, who noted that Dollard and Miller listed the four variables of learned behavior as drive, response, cue, and reinforcement and who suggested that these are identical to the variables stated in the following paradigm:

Bachrach, Erwin, and Mohr have presented the following explanation:

To modify Goldiamond's explanation of this paradigm somewhat, presenting a discriminative stimulus (S^D) in the presence of other constant stimuli (S^{S^C}) will occasion a response (R); whether this response recurs is contingent upon the conse-

quences (S^r) of that response (under these specific conditions) and the state variables (SV), usually referred to as "needs," "motivation," "deprivation," and the like, which make the consequences of the response effective in controlling it. Assuming that behavior is governed by its consequences under specified conditions, discriminative behavior can be produced, maintained, and altered if the constant stimuli, the discriminative stimuli, the response contingencies, and the state variables are specified and controlled.

This paradigm was used in a clinical case described by Bachrach, Erwin, and Mohr in which the experimental therapy program was planned according to the variables. The patient was an anorexic whose eating behavior was restored through operant conditioning techniques.

Mowrer's Two-Factor Learning Theory

O. H. Mowrer in a paper in 1939 offered, as Hilgard has observed, "the first clear statement of the anxiety-reduction or fear-reduction theory of reinforcement." Mowrer then theorized that much learning could be explained on the basis of acquired fear (anxiety) and that responses which reduce this anxiety are learned and maintained.

Contiguity and drive reduction. Mowrer suggested that anxiety responses are learned by contiguity. An adventitious association of a neutral stimulus with a painful stimulus conditions fear by contiguity in a fashion related to stimulus substitution in classical conditioning. In other words, a stimulus that in itself is not fear-evoking is accidentally presented at the same time as a painful stimulus; by simple conditioning (what Mowrer then called sign learning) the neutral stimulus becomes a conditioned aversive stimulus.

Any response that results in the avoidance or elimination of such a conditioned aversive stimulus (as an anxiety-producing event) is reinforced, even in the absence of other reinforcement, because the response reduces anxiety (drive). Once learned, these avoidance responses persist.

Mowrer considered that these were different from other types of conditioned responses in that there was no need for continued reinforcement to maintain the response. Other conditioned responses would extinguish in the absence of reinforcement; Mowrer felt that conditioned anxiety responses did not need the reinforcement of repetition of the original trauma. Although the responses were conditioned by contiguity, they were maintained by the reinforcing effects of drive reduction; classical conditioning of fear by contiguity was maintained by the subsequent conditioning (instrumental) of avoidance behavior by drive reduction.

Autonomic responses. Another differentiation Mowrer assumed in his two-factor theory was that fear responses are entirely autonomic. Emotional responses are involuntary and largely autonomic; instrumental responding is voluntary and largely under the control of the central nervous system. The classically conditioned fear response learned under con-

tiguity (sign learning) was, therefore, physiologically differentiated from the instrumentally conditioned avoidance responses maintained by anxiety reduction (what Mowrer came to call solution learning). The operant-respondent, type S-type R dichotomy is clearly in evidence here.

Some experimental evidence supported Mowrer's position that drive reduction is important in solution learning (instrumental conditioning) but that it is not crucial in the autonomically controlled anxiety response. Studies such as those reported by Mowrer and Solomon tended to support such a position although Solomon and Wynne suggested that fear responses are more than autonomic, involving such events as visceral and neuroendocrine responses as well as skeletal motor discharge. Thus central nervous system functions and voluntary behavior are also involved.

Mowrer has also invoked a model in which the stimuli conditioned to the onset of painful events acquire certain drive (anxiety) characteristics but those stimuli associated with the avoidance of or escape from pain become positively reinforcing. These two events, Mowrer described as responses of "fear" and "hope." In recent years, Mowrer's theorizing has centered largely around the development of neurosis and, in particular, the centrality of guilt and anxiety in emotional disorders.

Conclusion

In the application of some of the laboratory procedures derived from learning research, the behavior therapies have fallen heir to the very problems that beset the research scientists. Foremost among these is the problem of definition; the precise definition of such crucial concepts as stimulus, response, and reinforcement remains a theoretical and experimental problem. It is true, for example, that the definition of reinforcement when an experimenter is working with deprivation variables (deprivation of food or water, for instance) is a relatively uncomplicated experimental manipulation (although even here there are problems). But these problems are enormously complicated when the reinforcements are based on socially acquired drives, such as approval or attention, vaguely defined social events that appear of importance in human behavior. The precision with which experimental contingencies can be stated in both the laboratory and the clinic, then, is a continuing theoretical and research issue. A dedicated and meaningful interaction between research and clinical scientists in the development of learning theories and their application appears to be a most important and fruitful enterprise.

Suggested Cross References

The neurophysiological basis of learning is discussed by John in Section 2.10 in the chapter on basic biological

sciences in this area. For a discussion of a clinical application of learning theory, see Urban and Ford's section on behavior therapy (Section 34.2) in Area G, on psychiatric treatment.

3.4 MOTIVATION

ROBERT B. MALMO, Ph.D.

Under the general topic of motivation are many subtopics that are of interest from the psychiatric point of view, and this section focuses on these instead of attempting to touch on all points in the general area. For example, the topic of experimentation on drug dependency in animals has been selected not only because it is relevant for theories of motivation but also because these observations on animals have proved invaluable in placing the human problems of drug dependency in much clearer perspective. The second part of this section, drawing on data from human subjects, summarizes various clinical and experimental approaches to problems of human motivation. In addition, some current theoretical issues in this field are discussed. For example, the relevancy of data at the physiological level is considered. The affirmative point of view is in part documented with references to observations on neurological patients with operations on their frontal lobes and on psychiatric patients suffering pathological anxiety. The activation concept, which is introduced in the subsection on animal motivation, is also brought to bear on the human problem of anxiety.

The reader may well ask what some of these subtopics have in common and how they differ from those aspects of behavior dealt with under other headings, such as perception and learning. First of all, it should be pointed out that these topics are not mutually exclusive. For example, learning is certainly involved in becoming addicted to a drug, and when the drug is withdrawn, the resulting bodily changes are clearly perceptual phenomena. But given an organism with certain perceptual capacities and with a particular learning history, what is called motivation determines the nature and intensity of the behavior that will occur under certain conditions of environmental stimulation.

Animal Motivation

Biological mechanisms and homeostasis in motivation. In the mediation of learning and perception in mammals, the cerebral cortex plays a major role. But the limbic system (the hypothalamus in particular) appears to hold the main keys to understanding basic biological mechanisms responsible for motivating behavior. Neural and glandular processes mediated by this system as they appear to relate to motivation are the subject of extensive investigation at the present time. So numerous are these studies that even listing various lines of attack on basic biological motivational mechanisms is not feasible here, and this discussion, therefore, is highly selective.

Homeostatic mechanism for water regulation.

In order to provide a concrete reference point for the discussion that follows, the homeostatic mechanism for water regulation is described briefly. This mechanism has been chosen as an illustration because most of its aspects are well understood and because its principles of operation are typical of other homeostatic mechanisms.

Everyone knows that for the mammal to remain alive it must have water. When it has not had water for a period of time, its behavior is dominated by search for water and relief of thirst. But the whole problem of water regulation requires analysis at more than one level.

At the physiological reflexive level, water deprivation causes a release of antidiuretic hormone (ADH), which in its action on the kidneys reduces urine flow to a minimum, thus conserving water. Crucial for understanding this mechanism (and other fluid-regulating homeostatic mechanisms) is the *milieu intérieur* concept of Claude Bernard. In the case of water regulation, *milieu intérieur* refers to critical physicochemical relations between internal conditions of certain cells (called receptor cells or sensors) and the extracellular fluids (chiefly the blood supply) surrounding them.

Three questions are generally raised when the detailed workings of any homeostatic mechanism are being sought: (1) What critical changes in physicochemical conditions represent a significant departure from the optimal *milieu intérieur* (or other steady state)? (2) What sensor detects this departure from the optimum? (3) What is the line of transmission from sensor to the mechanisms responsible for effecting return to more optimal conditions? For water regulation, the answers are these: (1) The critical physicochemical changes are increments in effective osmotic pressure in extracellular fluids and intracellular volume changes. (2) The known sensors are neurons in the supraoptic nucleus of the hypothalamus, called "osmoreceptors" because their rate of firing increases with treatments that increase effective osmotic pressure in the extracellular fluids (for example, injection of hypertonic sodium chloride). Ishikawa, Koizumi, and Brooks, whose experiments with unit recordings established this fact, also found that the osmosensitive neurons responded to injections of hypertonic sodium chloride by an acceleration of firing, even after isolation from surrounding brain tissues. (3) It has been established beyond question that the supraoptic nuclei of the hypothalamus are involved in the production and release of antidiuretic hormone from the posterior lobe of the pituitary. The resulting conservation of water by the kidneys completes the reflexive chain, effecting return to more optimal physiological conditions.

At the reflex level, then, the picture is relatively complete. But renal water conservation is only a temporary measure, and, of course, the animal must seek

and ingest water in order to avoid fatal dehydration. What is known about neurophysiological mediation of these *behavioral mechanisms*? Water intake, as well as renal water conservation, is increased by tiny intrahypothalamic injections of sodium chloride. This indicates that, generally speaking, the sensors for reflexive and behavioral mechanisms share the same general area of the brain. But much more investigation is required on the behavioral aspect of this problem.

Other innate homeostatic mechanisms. The homeostatic mechanisms for regulation of temperature and of food intake have sensors in the hypothalamus. Microelectrode studies of cells in the hypothalamus—their reactions to changes in the *milieu intérieur* and their relations with other structures in the brain—are actively proceeding at the present time, with prospects of gaining important information in the next few years.

These innate homeostatic mechanisms serve to maintain an equilibrium essential to the health and survival of the animal, and their role in the motivation of animals is obvious.

Homeostatic mechanism for drug addiction. Drug dependence, though acquired and detrimental rather than beneficial, also appears to involve some kind of homeostatic mechanism. At least, the hypothesis that it is an acquired homeostatic mechanism seems useful in investigating this problem.

The physiological and behavioral aspects of morphine addiction (the most thoroughly studied addiction in animals) may be considered with reference to the following questions.

1. *How is the homeostatic mechanism acquired?* Considering the gaps in knowledge concerning the innate mechanism for maintaining the constancy of the water content of the blood (and the even greater gap in knowledge of other innate mechanisms), it is not surprising that much less is known about acquired homeostatic mechanisms, such as the one mediating dependency on morphine. Still, animal studies have thrown considerable light on the problem of how morphine dependency can be produced.

It does not matter whether the morphine is self-administered or administered by the experimenter. The only requirement for establishing dependency on morphine is that the administration be kept up regularly, day after day, until some objective criterion of dependency has been reached (usually the appearance of withdrawal symptoms). In Spragg's investigation of morphine addiction in chimpanzees, a typical course of morphine injections was 0.1 mg. per kilogram twice a day for the first 3 weeks, thereafter gradually raised to 2 mg. per kilogram and continuing at that level for several months.

When a dose was skipped or delayed for a few hours, some early signs of mild withdrawal were noted: slight rhinorrhea, drops of perspiration on the face, unusually large quantity of feces in the cage,

heightened irritability, and yawning. Animals differed in the time required to produce the first clear (withdrawal) signs of dependence from as early as 2½ weeks in one animal to 7 weeks in another.

When the animal sought out the injection on his own initiative, which happened after as long as 5 months of injections, Spragg called the animal "addicted." Examples of such purposeful goal-seeking behavior (usually after some break in the continuity of dosing with the drug) were: showing eagerness to be taken from the living cage by the experimenter when doses were needed, in clear contrast to behavior exhibited when taken from the living cage at other times; tugging at the leash and leading the experimenter toward and into the room in which injections were regularly given; exhibiting frustration when led away from the injection room and back to the living cage without having been given an injection; showing eagerness and excitement when allowed to get up on the box on which injections were regularly made; cooperating eagerly in the injection procedure; choosing a syringe-containing box (whereupon injection was given) in preference to a food-containing box.

2. *What sensor signals a need for the drug?* To put the question concretely, does the acquired homeostatic mechanism underlying dependence on morphine have a sensor resembling the osmoreceptor cells in the hypothalamus, which help maintain constancy of the water content of the blood? It is conceivable that certain hypothalamic cells, not already specialized for detecting dehydration or other such primary need states, may somehow undergo modification during the course of continuous morphine administration, thereby acquiring a sensitivity to the physicochemical conditions that underlie withdrawal symptoms in the morphine-dependent individual. This possibility would be susceptible to experimental attack if, by means of microelectrode recording, a search could be made for cells in the hypothalamus that fire at a faster rate just prior to a needed injection and reduce their rate of firing immediately after injection. At present, of course, this notion is speculative.

3. *What physicochemical conditions stimulate the sensor?* That is, what are the physicochemical conditions in drug dependency that correspond to the blood osmotic pressure in hydration constancy? According to Sourkes, the nature of the cellular adaptations in states of drug dependence (and tolerance) is an unsolved problem that presents a challenge to the physiologist and biochemist. Two kinds of theory about dependency may be distinguished. Both models postulate a form of cellular adaptation, and they are not mutually exclusive. According to one theory, the mechanism of adaptation requires that the drug be present on the neuron itself. According to the other theory, it is simply necessary that neurohumoral input be reduced; in other words, the reduction of nervous activity per se, and not the exposure of neu-

rons to the drug itself, is directly responsible for the development of withdrawal hyperexcitability.

4. *What central nervous system mechanisms act to restore equilibrium?* A reflex such as renal water conservation can work for a limited time only. Eventually, the animal must engage in purposive or goal-seeking activity in order to maintain conditions essential for life. For example, the dehydrated mammal must seek water. Similar goal-seeking activities are observed when an animal acquires an addiction, although they are not essential for maintaining life. Examples of purposive activity in chimpanzees suffering morphine deficiency have been mentioned. Such activities reflect at least two things: the strength of the dependency and the fact that the animal has learned the connection between his withdrawal symptoms and the means to eliminate them. It will be recalled that this learning did not occur until several months after withdrawal symptoms first appeared.

It was once believed that lower mammals like the rat could not become addicted to morphine. Compared with the chimpanzee, the rat is obviously limited in its range of responses instrumental to obtaining morphine. But after dependency (as shown by physiological withdrawal symptoms) had been produced by continuous injections over a period of several weeks, rats drank more fluid containing a morphine substitute than they drank prior to this period of morphine administration. Furthermore, H. D. Beach has shown that, after dependence was established, rats exhibited a preference for stimuli associated with the effects of morphine. Recently it has been shown by Weeks that, after dependence on morphine had been established, rats would press a bar to inject themselves with morphine by means of an indwelling injection device. (A plastic tube was passed under the skin from behind the ears to the front of the neck, where it was connected to a silicone-rubber cannula inserted into the rat's jugular vein, leading to the heart.) All these data indicate that taking morphine away from an addicted rat elicits goal-seeking behavior.

Experimental alcoholism in animals. Continuous administration of alcohol to animals for periods sufficiently long to produce dependence has rarely been carried out. Richter succeeded in producing dependence in three wild rats by restricting their fluid intake to a 10 per cent alcohol solution for a period of about 40 days. At the end of the period of force-feeding with alcohol, the rats continued to drink large quantities of alcohol, even though plain water was made available to them. One animal drank progressively more alcohol and less plain water, ate less and less, and died 30 days later. The course was one that closely parallels that of some human alcoholics.

In domesticated rats, however, Richter states that, even with more prolonged periods of forced feeding of alcohol, no such clear signs of dependence were ever observed. It is possible that dependency in the domes-

ticated rat could be demonstrated with still longer periods of exposure to alcohol. But Richter found no such difference between wild and domesticated rats when force-fed for 3 to 6 months on diets supplemented with increasingly higher concentrations of morphine sulfate. Wild and domesticated rats showed very similar withdrawal symptoms when the morphine sulfate was removed from the diet. Other workers have also reported clear cut dependency on morphine in domesticated rats. Again, absence of reports in the literature of dependency on alcohol in the domesticated rat may simply be due to the failure of investigators to administer alcohol in sufficient volume and over a long enough period of time. Still, the available evidence from animals is in line with clinical knowledge that dependency on morphine is much more readily established than is dependence on alcohol. That dependence is much more common in the case of tobacco than alcohol has been commented on recently by Brain.

It may be supposed that alcohol (or acetaldehyde) per se does not act on a receptor site in the nerve cell. In cases where dependency does occur after long continued heavy alcohol intake, the effect of alcohol may be much less direct than the effect of morphine. Recent research suggests such a possibility and is cited as an example of what *might* occur, although this suggestion is highly tentative. It seems possible that continuous ingestion of large quantities of alcohol may cause a deviation in the metabolism of norepinephrine and that in this process ethanol or acetaldehyde may promote the formation of catecholamine catabolites that resemble morphine. If dependency following heavy drinking of alcohol does turn out to involve some indirect process such as this, the fact that moderate drinking does not ordinarily produce dependency would be understandable, since moderate drinking would not ordinarily cause sufficient deviation of norepinephrine metabolism to promote the formation of morphine-like catabolites and subsequent dependency. Apparent proneness of certain individuals to dependency on alcohol might also be understandable in terms of their norepinephrine metabolism being more prone to interference, resulting in more rapid appearance of the addicting catabolites.

Or it may be that, compared with morphine, ethanol is a less effective blocking agent. Furthermore, it is logical to consider that individual differences in effectiveness of ethanol as a blocking agent may account in part for differences between individuals in their susceptibility to dependence on alcohol.

However, these are highly tentative suggestions. The nature of neural or other cellular adaptations in *all* states of drug dependence is still an unsolved problem, a problem urgently in need of further experimental work.

Immediate effects of drugs versus effects of withdrawal symptoms. The fact that even sated rats developed a preference for the goal box where they were injected with morphine was interpreted by H. D. Beach as evidence that the drug's immediate effects, after many exposures, had reinforced learning. Beach and others have demonstrated a second kind of reinforcement, that of relief from withdrawal symptoms in dependent animals. Unfortunately, some authors, perhaps through failure to be explicit, cause confusion in the minds of readers between immediate effects of the drug on nondependent animals and the

relief from withdrawal symptoms in dependent animals.

It appears that there are two motivational mechanisms involved, one mediated by the immediate reinforcing nature of alcohol or morphine and the other mediated by the relief of a *need* for the substance in the homeostatic sense. In the first case, when the animal chooses to drink alcohol, the alcohol is most probably not fulfilling a homeostatic need; instead it has gustatory or postingestional effects that are reinforcing. In the case of an addicted animal, however, the ingestion of an addicting substance is necessary to keep from becoming ill.

The literature dealing with alcohol ingestion by animals particularly suffers from confusion of these two mechanisms. Sometimes it is implied that conditions that strengthen the animal's preference for an alcohol solution *necessarily* make him significantly more prone to chronic dependency on alcohol. This, of course, is clearly wrong. As Richter's work has shown, domesticated rats can drink relatively large quantities of alcohol over long periods of time without showing withdrawal symptoms or other signs of dependency.

It is important, therefore, to distinguish between a shift in the *nondependent* animal's preference for alcohol and the *dependent* animal's intake of alcohol to relieve withdrawal symptoms. With this distinction clearly in mind, however, it is of considerable interest to investigate the question of what conditions, other than dependency, do increase preference for alcohol in animals.

Mammals below chimpanzee and man on the phylogenetic scale usually reject solutions of alcohol (with the exception of an inbred strain of mice that for some reason, as yet unknown, prefer certain alcohol solutions to water). Special conditions, however, have been shown to raise the animal's preference for alcohol solutions relative to plain water. Sex and strain differences are examples of constitutional variables that have been studied. Experiential variables have usually involved some kind of stress. In a recent study by McEwen at McGill it was found that alcohol intake patterns in rats could be modified under a number of conditions. These modifications were not due to simple correlations between intensities of stress in the variety of situations; they were dependent on complex interactions between strain, sex, and particular experiences.

Results of recent experiments on chimpanzees by Fitz-Gerald at the Yerkes Regional Primate Research Center are consistent with McEwen's findings of sex differences. Fitz-Gerald's data also indicate that chimpanzees resemble man in their enjoyment of alcohol. Unlike lower mammals (including rhesus monkeys), they drink alcohol voluntarily, without special inducements. It may be that a large brain with a relatively high proportion of cortex is required for

accumulation of residual tensions that are pleasantly relieved by alcohol.

Activation concept in motivation. The activation concept in its multifactor empirical form states that the level of physiological activation is determined by the interaction of internal and external factors. The changes in the *milieu intérieur* produced by water deprivation are examples of internal factors. In this situation the external cue factors interacting effectively with the internal ones to raise level of activation are, for example, perception of water or of other cues associated with the procurement of water.

Bélanger et al., at Université de Montréal have found that heart rate (HR) increases progressively with hours of water deprivation or food deprivation when the recordings are made under appropriate conditions of cue stimulation. The HR curve for rats in Figure 1 is a typical finding: HR in rats bar pressing for water showed progressive increment as a function of increasing hours of water deprivation. HR increment may also be regularly produced by depriving the animal of food. But food deprivation and cues associated with food must *both* be operative *together* for HR to show a rise. Even though the animal is deprived of food or water, HR does not increase in the absence of appropriate external cues. This observation provides important clues to the kind of neural mechanism that mediates goal seeking, motivated by deprivation of a basic need.

In the previous discussion of the mechanisms for water regulation, it was noted that the osmoreceptors in the hypothalamus react to changes in the *milieu intérieur* by acceleration of firing rate, even after isolation from surrounding brain tissues. The conditions

FIGURE 1. Heart rate level in relation to duration of water deprivation in rats. The rats were subjected to an increasing order of deprivation. (Data are from article by Bélanger, D., and Feldman, S. M. J. Comp. Physiol. Psychol., 55: 220, 1962.)

producing that acceleration are different from those accelerating HR because, obviously, afferent inputs are not required for accelerating the firing rate of the osmoreceptor cells, which appear to be under the sole control of the *milieu intérieur*. It may be that these osmoreceptor cells are specialized for taking part only in the reflex mechanism through which water is conserved by the kidneys.

It is possible that for a goal-seeking mechanism, where environmental cues are of critical importance, there are other cells, probably also in the hypothalamus, that accelerate firing in reaction to both internal (*milieu intérieur*) and external cue factors. This question can be attacked experimentally by recording from single cells in the hypothalamus of awake animals, following the paradigm of the Bélanger and Feldman experiment illustrated in Figure 1. Finding, under these conditions, that neural cells respond in a lawful quantitative manner (like HR) would provide strong support for one of the basic neural assumptions underlying the activation hypothesis.

The relation between hours of deprivation and frequency of bar pressing, as shown in Figure 2, takes the form of an inverted U. This finding is consistent with the prediction that there is a level of activation that is optimal for performance and that, on either side of this optimum, there is a performance decrement; the greater the departure from the optimum, the greater is the decrement in performance. It is probable that the freezing reaction in frightened animals represents impairment of normal motor sequences by overactivation. In any event, it is a good illustration of why it is important not to confuse overt activity and activation. Though inactive, an animal paralyzed with fear is nevertheless highly activated.

According to the activation or arousal concept, the

FIGURE 2. Number of instrumental responses in relation to duration of water deprivation in rats. The rats were subjected to an increasing order of deprivation. (Data are from article by Bélanger, D., and Feldman, S. M. *J. Comp. Physiol. Psychol.*, 55: 220, 1962.)

kind of neural activity considered here feeds impulses into organized neural cell assemblies, supporting the firing of their units in delicately timed sequences. According to this conception, optimal level of activation is that level of background firing (for example, of neurons in the hypothalamus) that provides the optimal facilitations of the organized neural activities (for example, in the cerebral cortex). It follows that too little or too much background firing of cells in the arousal system is deleterious with regard to organized neural firing (mediating performance).

Nonhomeostatic mechanisms of motivation.

When an animal is very hungry or very thirsty, his behavior is largely dominated by cues associated through learning with these organic needs. However, when the animal's basic needs are satisfied, his behavior is often directed by cues that have nothing whatever to do with seeking food or water or escaping from painful stimulation. Thorough experimental documentation of this point comes from extensive work on the curiosity drive in monkeys, in Harlow's laboratory at the University of Wisconsin. Harlow et al. demonstrated that monkeys will work for hours on mechanical puzzles with no reward other than solving them. Butler's experiments at Wisconsin showed that monkeys would work hard, hour after hour, just to have a small door open, allowing them the opportunity to look at objects in another room. They worked hardest to see another monkey there, but they worked nearly as hard to see an electrical train running.

This, of course, is one line of conclusive disproof of the drive reduction theory in its original form. As a matter of fact, these and other findings, such as Hebb's, show that far from seeking reduction in level of activation or arousal, animals will look for excitement. Even lower mammals like the rat manifest exploratory behavior that seems to have little or nothing to do with food seeking.

Another strongly motivated activity that does not depend on the animal's being in a deprived state is the Olds-Milner phenomenon of intracranial self-stimulation. Electrical stimulation of certain areas of the brain is clearly rewarding. Much remains to be learned about the mechanisms responsible for this remarkable phenomenon and the equally remarkable aversion to stimulation in other parts of the brain, first discovered by Delgado, Roberts, and Miller. But it is already clear that animals do seek positive stimulation. It is perhaps more correct to say that interactions between the relatively unactivated organism and its environment are often such that behavior is engaged more by stimuli that have activating than quieting effects.

Following the pioneering work of Hess and later refinements in technique by Delgado, current investigations are showing that rather complicated, well directed patterns of behavior can be elicited by means of stimulation through chronically implanted elec-

trodes in the brains of awake animals. Of particular interest to psychiatrists are the recent brain stimulation experiments by Flynn, Glusman, von Holst, and others on offensive-defensive behavior.

The importance of viewing motivated behavior as the product of complex (though potentially decipherable) interactions between external stimulation, hormonal influences, and neural influences is clearly illustrated in the work of Lehrman et al. on the reproductive behavior of ring doves. Normally, external stimuli are effective in eliciting a particular behavior only if the bird's reproductive cycle has progressed sufficiently far. But the behavior can be induced very much earlier in the cycle by injecting a hormone, provided the hormone is selected with knowledge of the succession of hormone secretions during a normal reproductive cycle. For example, if eggs are introduced into the cage before the doves have engaged in courtship behavior for 5 to 7 days, the birds will not sit on the eggs. Instead, they ignore the eggs while they engage in courtship. However, injecting both members of the pair with the ovarian hormone progesterone almost always elicits incubation behavior within 3 hours after the introduction of the eggs into the cage, instead of 5 to 7 days later.

An important key to an understanding of the neurophysiological aspect of these interactions lies in the fact that the activity of the pituitary gland, which secretes gonad-stimulating and other hormones, is largely controlled by the nervous system through the hypothalamus.

In the higher mammals, especially in the chimpanzee but to some extent even in the dog, copulatory behavior is more complicated than the stimulus-bound subcortically mediated behavior in lower mammals. The relative importance of the cerebral cortex in mating behavior increases in the mammalian series from rat to man.

Human Motivation

Activation. From the psychiatric point of view, it is a matter of great concern when a patient's work efficiency is chronically impaired by excessive tension. It is important, therefore, to try to gain a deeper understanding of the neurophysiological mechanisms underlying tension and its interactions with efficiency of performance.

Continuity from animal to human experiments on activation is illustrated in Figures 1, 2, and 3, graphs from two reference experiments: one with rats and one with human subjects. In both cases the curve for heart rate (HR) rises continuously, and the curve for performance takes the form of an inverted U. For the human subjects, different HR levels were produced by having the subjects squeeze a hand dynamometer, applying different degrees of force under the various conditions; the stronger the squeeze, the higher the HR. The performance measure was the score on a digit-to-symbol code translation task. Despite the

FIGURE 3. Heart beat and performance levels in human subjects under tension. (From article by Wood, C. C., and Hokanson, J. E. J. *Personality Soc. Psychol.*, 1: 506, 1965.)

great differences in subject, task, and means of producing HR change in the experiments with humans and with rats, the graphic functions obtained are remarkably similar from experiment to experiment. These findings are typical of results in a substantial number of similar experiments.

In other experiments with human subjects, graded verbal incentives have been used successfully by the experimenter in place of induced muscular tension to produce different levels of physiological activation. Performance on tasks of motor skill has been shown in some but not in all instances to vary predictably with the different activation levels. The physiological measures themselves are only imperfect indicators of central nervous (arousal) system action.

In all experiments with human subjects employing band-pass filters and integrators for quantification, electroencephalographic (EEG) changes concordant with the peripheral physiological changes have been found. It is presumed that the peripheral measures reflect activation level because the arousal system seems to have strong facilitation on peripheral effector mechanisms, in both autonomic and somatic spheres. It is not to be concluded, however, that a high level of activation is merely a state of extreme dominance of the sympathetic nervous system.

EEGs recorded along with various peripheral physiological measures, such as HR, respiration, and electromyograms (EMGs), have also been very useful in revealing an important difference between the rising functions just considered and a superficially similar but quite different kind of progressively rising physiological function called "physiological gradient." Unlike the rising activation level curves, where EEGs show progressive changes too, there are no systematic EEG changes accompanying the physiological gradients. These physiological gradients accompanying mental activity have been found in skeletal-motor and autonomic recording, commencing with the onset of the behavior sequence and terminating at its conclusion. Although it has been shown that these gradients do not represent increasing motivation or the like during the task, there is strong evidence indicating that the steepness of the gradients is a function of motivational level. It is presumed that there is some kind of mechanism that ensures the running off of a behavior sequence. Whatever the mechanisms are that furnish

the support for continuous productive mental activity, they seem to depend partly on normal exteroceptive sensory stimulation, since under prolonged conditions of sensory isolation, mental activity suffers markedly.

Achievement motivation. [There are individual differences in the plans of men. What are the conditions that make one man determined to achieve certain goals in a lifetime, and how are they different from those that operate to make another man content with a low level of achievement?

The hypothesis that the strength of achievement motivation can be gauged in a meaningful and useful way by analyzing the content of stories told from pictures, like those in the Thematic Apperception Test (TAT), underlies the extensive investigative work of McClelland et al. The research began with a demonstration that college students given instructions designed to heighten their intensity of motivation to perform well on certain tests produced (in the stories they wrote from the TAT pictures) more responses having to do with future achievement than students who were in a relaxed state at the time of writing TAT stories. The next stage in the experimental program was guided by the general hypothesis that individuals who obtain high TAT need (n) achievement scores under controlled conditions are normally more intensely motivated to achieve than persons who obtain low n achievement scores under the same conditions.

From the results of investigations so generated, it was concluded that intensity of motivation to achieve at any task in any particular situation is determined by at least two factors: (1) the achievement motive, that is, desire to achieve, and (2) expectancy of probable success or failure. McClelland has recently been engaged in highly successful field research, including some in underdeveloped countries, which has demonstrated that it is possible to teach businessmen to acquire n achievement and thereby to advance in business.

Expectancy \times value. The further development of this general line of attack has been pursued by Atkinson et al. in the expectancy \times value approach to motivation. The value factor refers to the common observation that there are marked individual differences with respect to values placed on certain objects or goals. Some students strive for A's, for example, and others depreciate the importance of grades, placing high values mainly on intellectual satisfactions or on extracurricular activities. The expectancy factor refers to the subjective probability that with expenditure of sufficient effort the object may be acquired or the goal reached.

It is appropriate here to call attention to the aphysiological character of Atkinson's theory and to suggest that theorists who look at neurophysiological data will probably be able to construct a more comprehensive and useful theory than theorists who choose to ignore those data. Atkinson states that his approach

is not "explicitly guided by any preconceptions concerning neurophysiology." However, Hebb has argued that behavior theorists who disregard contemporary neurophysiology and neuropsychology may unconsciously fall back on outmoded neural conceptions in their theoretical formulations. Aphysiological theorists are disinclined to speculate or to deal with data from two levels of description, neurophysiological and behavioral. But it seems there should be a two-way street here. Not only is behavioral research enriched by an appreciation of neurophysiological discoveries and observations in neurological clinics, but tracing relations between the behavioral and neural levels of description must inevitably be heuristic for research at both levels.

For example, the expectancy \times value theory surely would be enriched by observations of neurological patients, especially those showing motivational deviations. B. Milner has found that frontal lobe patients break test rules more often than other patients do. For example, in performing a stylus maze test, they would push ahead instead of going back to the point where they made an error, or they would move along diagonals (against the rules). It was not that they didn't realize these things were wrong; it seemed they just couldn't control their impulsiveness. When progress toward the goal came into conflict with rules, the value system normally respecting rules was shown to be abnormally weak in the frontal lobe patients. What is there about frontal lobe mechanisms that make them essential for such value systems to have normal control over behavior? This question seems highly relevant for the expectancy \times value theory of motivation, and the theory should gain considerably in scope if it took such data into account.

Drive (D) \times habit theory. As in the case of the activation concept, so too in the $D \times$ habit theory there are points relevant to the general problem of anxiety in its effect on performance. Using manifest anxiety scores (MAS) from a questionnaire to divide human subjects into high MAS and low MAS groups, Spence and Taylor have compared the two groups with respect to performance on various tasks. The main general finding is that high MAS scorers are favored over low scorers on simple tasks in which potential competition between conflicting responses is low and that low MAS scorers are favored in more complex tasks. These authors are careful not to extrapolate their findings to psychiatric patients suffering pathological anxiety. (Their subjects were usually university students.)

Their work stemmed from the drive \times habit formulation of Clark Hull, according to which habit strength is increased with an increase in drive, such as that produced by food or water deprivation (and later, following Mowrer's work, also anxiety). In Hull's terminology, D represented general drive, the combined effects of various specific drives. Hull proposed a multiplicative relation between the nonspe-

cific general drive (D) and the behavioral manifestation of habit strength: the greater the D , the stronger the response.

In an extensive series of experiments with human subjects, Spence and Taylor have attempted to verify the $D \times \text{habit } (H)$ strength hypothesis (earlier investigated with animals), and they have accumulated a certain amount of supporting evidence for better performance going along with high D . When high D (as measured by the MAS questionnaire) is found associated with *lowered* performance, the performance decrement is accounted for in terms of competing responses interfering with the correct response. But some very simple responses show the inverted U relation to drive strength instead of the monotonic relation predicted by the $D \times H$ hypothesis. These cases seem impossible to account for in terms of the competing response notion of the Hull-Spence formulations: they seem to require some kind of explanation like that provided by the activation concept.

Current motivational concepts. Certain terms appear frequently in the literature on human motivation. The concept denoted by each term gains clarification by reference to the experimental procedures employed in investigating each specific problem. Therefore, the main purpose of the brief remarks that follow is to indicate in each case the kind of experimental approach employed.

Dependency. On the basis of studies with children, Sears regards dependency as an acquired drive, one that is or may be developed very early in a child's life. The topic has received relatively little systematic study with adults.

Level of aspiration. This term has been used by Lewin and his students and involves a procedure in which the subject is asked to say how he will do on the next trial of a task. For example, a subject engaged in a dart-throwing task may be asked before his first throw what number he expects to hit. After the throw and before the next trial, he is asked again to predict his performance, and so on for several trials. The relation of level of aspiration to achievement motivation is discussed in detail by Atkinson.

Ego involvement. The term ego involvement, in the investigative sense, refers to observations of the individual in situations where persons, groups, or values with which he identifies are called into question. This topic is discussed by Cofer and Appley.

Cognitive dissonance. This is Festinger's term, and it means incongruity or disharmony with respect to such matters as expectation and actuality. An A student who makes a B experiences a tension not experienced by a B student making the same grade. In general, dissonance occurs when there is a palpable disparity between two experiential or behavioral elements. It is postulated that cognitive dissonance produces a tension state (like hunger) that is motivating. The kinds of experimental investigation generated by

the theory are illustrated by the following question: How does dissonance in different degrees affect the individual's inclination to seek out or to avoid new information? What are the reactions of persons who are forced to consider information or propaganda they would normally have avoided?

Perceptual defense. The concept of defense here resembles that of repression, unconscious resistance against the perception of things that are disagreeable or disturbing. Attempts to demonstrate such a phenomenon in the laboratory have invariably been challenged by critics who offer what they consider to be more parsimonious explanations of the reported observations. Probably the most promising line for future investigation is in the study of idiosyncratic perceptual defensive reactions, that is, in the study of individual differences in perception rather than in the study of average reactions from groups of individuals.

Intrinsic motivation. J. McV. Hunt defines intrinsic motivation as being "inherent in the organism's informational interaction with circumstances through the distance receptors and in its intentional, goal-anticipating actions." Promising new experimental work with human infants by Hunt et al. is concerned with the possibility of hastening certain aspects of development by providing the infant with interesting and varied exteroceptive stimulation.

Psychoanalytic motivation theory. From the historical point of view, Freud's contribution to the psychology of human motivation should come first, of course. Freud's writings were probably the most powerful single influence initiating scientific investigations of human motivation. The whole course of experimental psychology was changed by the combined attack of Freud and the behaviorists on structural psychology, which had become lost in sterile introspective exercises. From Freud's observations it was plain that a full understanding of the causes of human behavior could not be gained from conscious introspections. Clearly much of behavior is determined by unconscious mental activities, activities that the person is unaware of and consequently cannot report on.

Atkinson points out that Freud, the scientist, regarded his conceptions as tentative. An appropriate concluding statement to this consideration of the study of motivation is provided by the following quotation from Freud (cited by Atkinson):

We must be patient and wait for other means and opportunities for investigation. We must hold ourselves too in readiness to abandon the path we have followed for a time, if it should seem to lead to no good result. Only such 'true believers' as expect from science a substitute for the creed they have relinquished will take it amiss if the investigator develops his views further or even transforms them.

For the rest we may find consolation in the words of a poet for the slow rate of progress in scientific knowledge:

'Whither we cannot fly, we must go limping.

The Scriptures saith that limping is no sin.'

Since modern day psychiatry, psychology, and ethology can all trace their origins to work carried out in the last decades of the 19th century, it seems rather paradoxical that psychiatry has been more sympathetic to and made greater use of ethological concepts than has psychology.

The deep chasm that has existed until recently between ethology and psychology can be attributed to several factors. One is certainly the cavalier use of the term "instinct" by psychologists such as McDougall early in the 20th century; such usage eventually reduced the concept of instinct in the United States to a catch-all explanation for behaviors that could not be easily understood in other terms. Concurrently, J. B. Watson attracted attention with his behavioristic theory, which appealed to psychologists because of its parsimony and its promise of explaining behavior on the basis of simple relationships between the individual and his environment. The third major factor leading to the negative relationship between psychology and ethology was a fundamental lack of communication between researchers in Europe and in the United States, which lasted until the late 1940's.

In contrast, ethology and psychiatry have their roots deep in the same soil. Initial developments in both areas stem from the work of Europeans, and ethological ideas were familiar to many psychiatrists who transported them to this country in the period before World War II. Besides, there were no disrupting factors for psychiatrists in adapting ethological concepts to the phenomena with which they were confronted.

Development of Ethology

Some of the basic principles of ethological research can be traced back for several hundred years. So the

modern study of animal behavior, rather than implying that ethology is a new approach to behavior, seems to reflect a rediscovery of the relationship of the concepts and orientation of ethology to present day problems in behavior.

Natural behavior. Basic to the ethological approach to the study of behavior is the emphasis on familiarity with the natural behavior of the organism to be studied. Once the observer is acquainted with the functioning of the animal in its natural environment, he can vary the environment and learn with certainty how it influences the animal's behavior. This principle is well illustrated in the work of Baron von Pernau, a German zoologist whose major treatise was published in 1716 and who provided detailed descriptions of behavior peculiar to each of many different species of birds—what we now call species-specific behavior.

His most important finding was that in some songbirds the species-specific vocalizations of the adult are learned early in the life of the animal, but that in other species these vocalizations are completely innate. To reach this finding, he used a technique known to present day ethologists and to those dealing in psychological research as the deprivation experiment. Once familiar with the normal behavior of these species, von Pernau raised birds of several such species in an environment where they were deprived of contact with other members of their own species. Under these conditions, songbirds of some species exhibited species-specific vocalizations at the proper time in development; but birds of other species grew to adulthood employing the vocalizations and songs of the nonspecies members with which they had been raised. They retained these vocalizations even though they were later given an opportunity to live with their own species.

Species-specific behavior

Instinctive behavior. The next major contribution to ethology was provided by the work of the French naturalist and scientist Reaumur in the middle 18th century. Reaumur wrote of innate behaviors in a wide range of species, observing that many species-specific behaviors occurred even though the young animals were removed from the mother shortly after birth and reared without the companionship of species members.

Innate complex behavior. Reaumur was also the first to point out that, in some cases, rather complex behaviors involving the use of special organs must be innate, since the behavior patterns adapted for the use of these organisms are performed before the organ has developed and cannot have been learned through experience. An example may make this clear. Young goats push each other with their heads before they have horns, and young boars try to slash each other with sideways blows of their heads long before their tusks have developed.

Evolution of behavior patterns. The concept of innate or unlearned behavior was given a great impetus by the work of Charles Darwin. He wrote of complex behavior patterns that were characteristic of a species and required no learning, since they appeared full blown immediately after birth or after hatching. Darwin's major contribution in this area was his approach to behavior from the genetic point of view. He treated innate behaviors in the same way that morphological characteristics were dealt with and found ample evidence for the evolution of behavior patterns.

"Blind" behavior. Another person prominent in the study of instinctive behavior during the 19th century was D. M. Spaulding. As a result of observing the behavior of many animals, he felt that instinctive behavior patterns were fundamental in the behavior of many species and was the first to call attention to the "blind" aspect of certain instinctive behaviors. Spaulding noted that, when he presented himself to newly hatched chicks in place of the mother, these animals followed him and reacted to him in the same way that chicks normally do to their natural mother. In this case, the young animals had a built-in response (following), which was released by the first object encountered after hatching, but the animals did not have an innate conception of what this object should look like.

Writing in the early 1870's, before Mendel's work on genetics had been widely recognized, Spaulding emphasized the genetic transmission of instinctive behavior patterns and hypothesized that this transmission took place in the same way that physiological characteristics are passed on from generation to generation. Spaulding's work was the precursor of the concept of imprinting.

Umwelt. Jacob von Uexküll, whose writings encompass a 25-year period from the early 1900's to the middle 1930's, developed the concept that each organism has its own particular *Umwelt*, which means essentially that, of the vast complex of physical stimuli in an animal's environment that could possibly affect his behavior, he may respond to only a few. It was also demonstrated in von Uexküll's work that instinctive behavior is specifically geared to the survival of the individual and of the species.

The behavior of simple organisms clearly illustrates these concepts. The common woodtick, for example, apparently responds to only three environmental stimuli during the greater part of its adult life. First, as a result of photosensitive receptors in its skin, it goes to the brightest part of its environment. This leads the tick to climb a bush or tree. Second, it responds to the scent of butyric acid, which is given off by warm-blooded animals, by releasing its hold and dropping from the branch. Third, on encountering a temperature of approximately 37° C., such as that of a mammal, it attaches itself to the spot and gorges itself on blood before falling to the ground to lay its

eggs sometime later. The relationship between these stimuli and these responses is innate in origin, and certainly each is designed to ensure survival of the species.

In more advanced organisms, these relationships are not so easily seen. At the human level, any study of instinctive behavior mechanisms is confounded by the complexity of the physical and social environment that man has created for himself. Since man's technology has developed much more rapidly than he has changed through genetic adaptation, it may be necessary to ask how a bit of behavior, which we suspect is innate, fitted into the environment of primitive man and contributed to his survival.

Appetitive behavior and consummatory responses. Wallace Craig brought out this complexity in the behavior of more advanced species when he made the distinction between appetitive behavior and consummatory responses. Appetitive behavior is essentially variable, though goal-directed, and can be changed through experience with the environment. The consummatory response, however, is stereotyped in form and instinctive in nature. This distinction has illustrated that behavior may vary from species to species as the two components vary.

Instinct-training interlocking. Among contemporary ethologists, Konrad Lorenz has contributed to the greater understanding of instinctive behavior and has both clarified earlier concepts and presented new ones concerning the functioning of instinctive behavior mechanisms. Lorenz amplified Craig's idea of appetitive behavior and consummatory responses into a system which he has called instinct-training interlocking. This term implies that the behavior of a particular organism is a continuous process of smooth integration of learned aspects of behavior with the instinctive components. Those behaviors that are learned lend a flexibility to behavior and lead to greater adaptability in varying environmental situations. Those components that are instinctive insure that certain reactions to certain stimuli will be made without the necessity of learning; instinctive components are most clearly seen in cases where, if learning were required, the possibility of survival would be greatly diminished.

Action-specific energy. Another major contribution of Konrad Lorenz was the concept of action-specific energy. He observed that, with repeated performance, there was a waning in the ease with which instinctive behavior patterns could be elicited and that this waning was not related to general fatigue of the animal. After an interval of nonelicitation, however, the suitable environmental stimulus would again lead to the instinctive response. Lorenz concluded that for each instinctive response there was a certain amount of energy available and that, when this energy was depleted, the response would no longer be exhibited but that, with rest, the energy reservoir would be replenished. It should be kept in mind that

studies of action-specific energy are carried out under circumstances that do not simulate the normal environment of the animal, since under natural conditions the function of the response is served the first time it is released by the environmental stimulus.

Vacuum activity. Lorenz's belief in the existence of action-specific energy was strengthened by observing behavior he termed vacuum activity. In the absence of the appropriate environmental stimulus, an animal showed a precise instinctive response, just as though the stimulus were present. Since this occurred primarily in animals deprived of their natural environment, where the stimulus appropriate to the response would be encountered, Lorenz interpreted this behavior as a spilling over of action-specific energy into behavior when this energy had built up as a result of the long period of response inactivity.

Displacement activity. One of the first books devoted exclusively to the study of instinctive behavior was written by Niko Tinbergen and appeared in 1951. Tinbergen emphasized the relationship between internal factors, such as hormonal conditions, and external factors, such as distinct environmental stimuli, in leading to instinctive responses.

Another concept discussed in Tinbergen's first book is displacement activity, which had been noted previously by other ethologists. This behavior is most clearly seen in situations where there is a conflict between two instinctive behavior patterns and the expression of one or the other pattern is physically prevented or overwhelmed by ambivalence. As a consequence, the animal exhibits a third instinctive behavior, usually quite unrelated to either of the behaviors in conflict with each other. It is as though when blocked, the neurological activity generated by the two conflicting behavior patterns sparks over into the third behavior, which is inappropriate to the situation. For example, a chicken faced with an opponent that it would like to attack but that is clearly superior in size or weight may, instead, start to peck at nonexistent food.

Neurological mechanisms. Until recently, the concepts of action-specific energy and displacement activity have been in the realm of hypothetical constructs, together with such psychoanalytical ideas as sexual and aggressive energy systems. The research of Erich von Holst has done a great deal toward solidifying the position of neurological mechanisms that function in association with both types of behavior.

The basic technique used by von Holst involves the implantation of electrodes in the brain stem of chickens. Through electrical stimulation of various points in the brain stem, von Holst has been able to elicit almost all the simple and complex behavior patterns normally exhibited by the species. Activation through electrical stimulation seems to simulate the activities

of these areas in the same way as normal neurological processes.

The finding of centers in the brain stem directly related to behavior patterns in chickens supported some of the ethological ideas about the organization of behavior. Further support came from results that appeared to simulate action-specific exhaustibility. In these cases, von Holst found that, with repeated stimulation, the threshold for the response rose rapidly and there was repeated response evocation until the point was reached where even a large amount of current would not evoke the response. However, after the chicken had a period of rest, it was again possible to get the response with the normal voltage. Von Holst, in a way, was artificially replicating those results that had been obtained by others, who elicited and exhausted the response with an external stimulus.

If even greater consequence were experiments in which antagonistic drives and responses were simultaneously stimulated. This sort of experimentation fits the paradigm of displacement activity as exhibited by an animal in its natural environment. Although, in some cases under electrical stimulation, one response would supersede the other, there were also cases where, just as with displacement activity, a third response, completely unrelated to the two stimulated, was evoked during the experimental session. And whenever the two particular responses were stimulated simultaneously, it was always the same displacement response that was shown by the animal, indicating the same type of lawfulness found in nature.

Innate releaser and fixed action pattern. The innate releaser is a stimulus in the environment that serves to trigger a specific innate behavior on the part of the animal. This stimulus can be received by the organism via any of the sensory modalities, although the most common are visual and auditory stimuli. The response elicited by an innate releaser is stereotyped in manner and does not vary from one elicitation to another. For this reason, these instinctive responses have been termed fixed action patterns.

To the inexperienced or casual observer, the relationship between innate releasers and innate responses looks like a stimulus-response relationship based on learning. However, a response must meet several criteria before it can be called a fixed action pattern and thus qualify as an instinctive response. These are: (1) the behavior involved in a response must occur in exactly the same way each time the stimulus is presented; (2) the complete response must occur at the first presentation of the releaser before there has been a chance for learning to take place; (3) the response must occur in all members of a species; and (4) the response must occur in individuals raised in isolation from species members.

Ethology and Psychiatry

Since the middle 1950's, a number of articles in the psychological and psychiatric literature have used

ethological concepts to support certain psychiatric hypotheses that have developed over the years. The ethological concepts of action-specific energy, displacement activity, and imprinting have, apparently, been the most useful to the psychiatrist.

The basic phenomena with which the ethologists have concerned themselves and the hypotheses that relate these phenomena to human behavior and human development represent an effort to solve some of the behavioral problems that have confronted psychiatrists. In this effort, man is viewed as a member of the animal world rather than as a separate and distinct species exempt from developmental and behavioral regulations applied to the behavior of other animals. Clearly instinctive behavior patterns are designed to maximize the biological survival of the individual as a species, and this function is implicit wherever instinctive mechanisms are postulated as operating at the human level. Just as clearly, studies involving the concepts of action-specific energy and displacement activity have provided working hypotheses as to the internal control and organization of instinctive behavior patterns.

Action-specific energy

Relation to Freud's psychic energy. Freud's use of psychic energy as the basic force in human behavior has probably been one of the most difficult of his theories to accept. Psychic energy, obviously, cannot be visibly seen and studied but must be inferred from actions of the individual. The independent development of the concept of action-specific energy associated with instinctive behavior patterns has given great support to Freud's theory. There is a strong similarity between the two concepts, and action-specific energy can be precisely studied at a behavioral level, even though its physiological bases are just beginning to be elucidated.

Mechanisms and function. Konrad Lorenz presented the underlying mechanisms and function of action-specific energy in two of his earlier papers (1935 and 1952) and gave examples of how the concept operates at the behavioral level. Basically, action-specific energy serves both as a factor that energizes instinctive behavior patterns and as a motivational factor so far as the behavior is concerned. As the term implies, Lorenz felt that there was at any given time a quantifiable amount of energy available for the activation of a particular bit of instinctive behavior. Once this reservoir of energy was completely drained or depleted as a result of continuous activation of the response, a time interval was required in order for the supply of energy to be replenished.

The clearest example of this aspect of action-specific energy can be seen in behavior patterns that are used in nature with relative infrequency. For example, a bird, the whitethroat, has a characteristic response of feigning injury in order to lure a predator away from the nest. As the predator approaches the nest,

the bird hobbles away with one wing hanging, as though it had been seriously injured. When a safe distance away from the nest, however, and certainly before being caught by the predator, the whitethroat takes to the air and returns to the nest. This response appears in complete detail the first time the experimenter approaches the nest. Should the experimenter approach the nest again shortly after the bird has settled, the response is made again, but to a lesser degree. And on the third approach, immediately after the bird has resumed its brooding, no response is made at all. If the entire process is repeated several times, with an interval of a few days between sets of trial, exactly the same thing will happen each time the response is tested.

The draining of the energy available for such responses is not due to general physical fatigue, since other responses are readily performed when the innate response in question can no longer be elicited. The phenomenon is due neither to adaptation to the eliciting stimulus nor to fatigue but, rather, to the depletion of the energy used specifically for that response.

Displacement activity. Kaufman has pointed out the similarity between Freud's model of libidinal energy and the concept of action-specific energy. For a clearer picture of how action-specific energy might be applied at the human level, it is necessary to go into a more detailed account of the closely allied phenomenon of displacement activity.

As noted earlier in this section, displacement activity refers to a response that occurs out of its normal environmental context. In other words, the response, which is instinctive in nature, appears in the absence of the usual stimulation normally associated with the response. However, in contrast to vacuum activity, displacement activity can be directly related to an environmental situation.

Conflict of drives. Tinbergen outlines two situations in which displacement activity is most likely to occur. The first one is a conflict of two strongly activated drives that are antagonistic to each other. Displacement activity of this type is seen commonly in a fish, the male three-spined stickleback, when fighting behavior and escape behavior are simultaneously activated. In this species, each male has his territory containing the nest, which is closely guarded against the encroachment of another male. The sight of another male coming into the territory serves first as a sign stimulus for the male to respond with a threat posture. In some cases, this posture alone is sufficient stimulus to cause the strange male to leave the territory. At other times, if the strange male has no territory of its own and he is motivated by a strong internal drive to establish a territory and start nest building, he may not leave the established territory when threatened this way. The established male will then attack the strange male, but as he approaches the edge of his territory, this attack response weakens and starts to conflict with his flight tendency. At this point, when

the conflict between the two drives is such that each is at about the same intensity, the stickleback exhibits a third instinctive behavior pattern, displacement digging, which is completely out of the context of the situation. The movements involved are exactly the same as those seen during the time the male is building the nest. This, of course, clearly belongs to a set of innate responses that have nothing to do with either fighting or fleeing behavior.

In effect then, when behavior is blocked by the conflict of drive states and motor patterns involving those drive states, pressure is released by running off into a third behavior pattern. This is, of course, a purely conceptual way of dealing with the phenomenon.

Lack of external stimulus. The second situation in which it is common to see displacement activity occurs when there is a strong internal motivation for a consummatory act but the external stimulus necessary to release the act is lacking in the environment. This is most commonly seen in sexual responses, with hormonal levels acting as the internal stimulus and certain social responses in fellow species members serving as releasers for the sexual behavior.

Physical implications. Both action-specific energy and displacement activity suggest that there is an energy system controlling behavior, which under certain conditions must be discharged in overt activity, and that there is a built-in neurological relationship between internal excitation and the stereotyped fixed action patterns of instinctive behavior. Both types of situations leading to displacement activity indicate that, when the appropriate channel for the discharge of action-specific energy is blocked, the energy spills over into another channel, as the result of activity in the central nervous system, rather than leading to random activity.

Social implications. The transition from instinctive behavior, as we have discussed it in relation to action-specific energy and displacement activity, to the traditional psychoanalytic concept of instinct as outlined by Freud primarily involves a shift from purely physical relationships at the animal level to physical and psychic relationships at the human level. At the animal level, there is a specific, genetically determined relationship between internal excitation, a releaser in the environment, and the response, and this relationship cannot be altered through experience. At the human level, there is a certain amount of genetic determinism regarding psychic energy, which may be invested in the sexual and the aggressive drive, but the stimulus objects to which this energy is cathected can be the mental representations of these objects and may be determined through individual experience.

The possibility exists that, without the complex sociological pressures to which man has been subjected, there would be a lawfulness in the development of human behavior similar to the organization found in animal behavior. In fact, it can be predicted from what we know about the genetic determinants in the

behavior of men that without civilization man would nevertheless exhibit behavior and behavior patterns that would make him little different, to the best of our present knowledge, from the socially organized small groups of other primates. The blocking of the discharge of sexual and aggressive energy into natural channels, due to society's not permitting the individual certain modes of instinctual gratification, could be analogous to the situations leading to displacement activity in the examples from animal behavior.

Psychiatric implications. Contemporary psychiatrists have used the ethological concept of displacement activity in at least three ways in relating ethological principles to human behavior. Although each approach is somewhat different, each seems to provide a valid working hypothesis at the human level.

The fact that many displacement activities at the animal level do not serve to maximize the survival of the individual or species has been emphasized by Weigert. In a way, this relates displacement activity to neurotic anxiety, which Freud considered to be the result of a frustrated libidinal impulse and which is, of course, basically detrimental to the individual. This interpretation of displacement activity emphasizes the nonfunctional aspect of neurotic behavior. At the same time, it must be kept in mind that the conflict situation experienced by the individual may, under certain circumstances, result in the sublimation of libidinal energy into activities condoned by society. This has been pointed out by Freud.

Kaufman has postulated that, in addition to the sexual and aggressive instincts in men, there may be an instinct for flight. He has drawn heavily on work with displacement activity, since many such behaviors are the result of a conflict between aggressive and flight reactions. Kaufman points out that at the animal level sexual behavior, aggression, and flight are all built-in tendencies and that the same thing is likely to be true of man. He feels that this theoretical paradigm would be beneficial in the treatment of patients whose shyness and timidity (low intensity manifestations of a flight tendency) would not have to be construed as a reaction to hostile or sexual impulses but could be interpreted as a drive in its own right.

A third way of viewing displacement activity is that taken by Ostow. After drawing some parallels between the psychoanalytic concept of instinct and the ethological concept of instinct, he used displacement activity to illustrate a logical progression of development in man. Dealing only with the sexual instincts, he hypothesized that gratification of these instincts takes different forms during different periods of development and that the mechanism that leads from one form to another functions in the same way displacement activity functions in lower animals. As one mode of gratification is inhibited, the instinct accepts another mode of gratification. In this way, he traces the sexual aims in psychic development through oral, anal, phallic, and genital stages.

Imprinting. Research on early experience has shown that the environment of an animal early in life can play an exceedingly important role in later adjustment and later adult behavior. This point is made most clearly in the phenomenon that has become known as imprinting, derived from the German term *Prägung*, which is attributed to Konrad Lorenz.

Species recognition. Lorenz observed the behavior of newly hatched geese both with the natural parents and with himself when he presented himself to the young animals as a parental object before they had an opportunity to associate with their parents. Later in life, the animals treated members of that species to which they had first been exposed as fellow species members. Lorenz concluded that this species recognition was imprinted onto the nervous system of the young animal during the first period of exposure after hatching.

As a functional piece of instinctive behavior, imprinting serves its purpose well. Under normal conditions, the first object seen is, of course, the natural parent, and the rapid attachment of the young to the parent is necessary for the survival of the young animal. During the first days of life, the parent broods the young, protects it from predators, leads it away from dangerous situations, and takes the animal to food objects in the environment. None of this would happen if the young animal did not almost immediately become highly attached to the parent and follow it under all circumstances.

Contrasts with association learning. Since the early 1950's, imprinting has been studied in the laboratory, particularly in the United States. Ramsay and Hess in 1954 showed the feasibility of studying imprinting in a laboratory situation, and their work has been reviewed in papers by Hess in 1959 and 1964. The results of their laboratory work can be stated in five

FIGURE 1. Imprinting—test apparatus. The apparatus used in the study of imprinting consists primarily of a circular runway, around which a decoy duck can be moved. In this drawing a duckling follows the decoy. The controls of the apparatus are in the foreground. (Reprinted by permission from Hess, E. H. *Imprinting*. Science, 130: 134, 1959.)

points that seem to make imprinting quite different from the association learning commonly studied by the experimental psychologists.

In the waterfowls studied, there is a critical period that is sharp and distinct. In the case of mallard ducks, for example, there is a peak of sensitivity to the imprinting phenomenon at about 16 hours after hatching, and this sensitivity drops rapidly thereafter. By 32 or 48 hours after hatching, the increased fear response of the animal appears to interfere with further imprintability. Similar critical periods have been found for other animals as well. Although not all the critical periods are within the 1st day, they have all been found to occur in the very early life of the organism.

The use of certain drugs, particularly muscle relaxants, interferes completely with the acquisition of the imprinting effect. These same drugs do not interfere at all with the normal acquisition of a discrimination such as one would experimentally study in a psychological laboratory.

Massed practice is more effective than spaced practice as far as imprinting is concerned. In addition, by the law of effort, the imprinting effect is positively related to the amount of energy expended by the animal in going to or in attempting to go to the imprinting object. In this case, too, there is a difference between imprinting and association learning.

In imprinting, primacy and recency work in a way completely different from the way they work in association learning. In imprinting, it is clearly the first thing learned that is retained, whereas in association learning the animal tends to respond to the last meaningful stimulus.

The effect of punishment or painful stimulation in imprinting has a result quite the opposite of what occurs in an association learning situation. This study is perhaps of particular interest to psychiatry.

FIGURE 3. Effects of punishment during imprinting. This chart shows the number of feet that chicks of two major treatment groups, one shocked and the other not shocked, followed the imprinting object and their age at first exposure to the imprinting situation. The shocked chicks were given 11 heavy shocks of 3-milliamper intensity, $\frac{1}{2}$ -second duration, during the imprinting experience; the nonshocked control chicks were given none. (Reprinted by permission of Holt, Rinehart and Winston from Hess, E. H. *Ethology*. In *New Directions in Psychology*, Chapter 3, 1962.)

In this study (Kovach and Hess, 1963), data are reported on groups of chicks at an age close to the critical period, 18 hours, and well beyond the critical period for imprinting, 48 hours. At each age, chicks were given electrical shocks while in an imprinting apparatus with a "blue ball" (parent object); control chicks received no shock. At the age of 48 hours, those chicks receiving shock avoided the parent object which was evidently associated with the shock. However, those animals that were shocked in the same way during the optimum period for imprinting actually followed the parent object significantly more than the control animals, which had not received shock.

This result may be perplexing from the standpoint of association learning, but it is not unreasonable from the standpoint of instinctive behavior and the normal survival value of such behavior. For example, if in the natural situation the young animal were to be stepped on by the parent before he leaves the nest, it would not be biologically useful to have the young avoid the parent, leave the nest, and die. If anything, there seems to be an overcompensation for any punishment associated with the parental object, since the animals receiving shock did follow better than the control animals. The animal, in a painful situation at that moment when it depends on the parent to a tremendous degree to survive, seeks to get even closer to the parent object.

At least one paper published in the psychiatric literature seems to tie in this phenomenon with behavior in young children, where there is also a dependency relationship between the child and parent. In discuss-

FIGURE 2. Critical age for imprinting ducklings. Ducklings are most effectively imprinted at the age of 13 to 16 hours, as depicted by this curve, which shows the average test score of ducklings imprinted at each age group. (Reprinted by permission from Hess, E. H. *Imprinting*. *Science*, 130: 135, 1959.)

ing ethological concepts as they might apply to moral masochism, Menaker takes the position that psychic development is as important to the child as physical development and that when the mother is "unloving, powerful, exploitative, and dominating" in relation to the ego needs of the child, the child will, as the weaker member of the pair, become submissive. At the same time "it creates an idealized image on which it can then be nourished for purposes of identification, ego formation, and ultimate survival." Menaker relates this type of behavior to innate mechanisms of submission that prevent species members from killing each other. It appears that the child, who is essentially in a punishing relationship with the parent and who reacts by idealizing the parent and picturing her as all powerful and loving is doing exactly the same thing a young chick does during its critical period when it follows a parent object even more closely after being punished in the presence of that object. It is not impossible that both mechanisms are operating on the unconscious level, are vital to the survival of the organism, and parallel each other on some phylogenetic basis. Just as nature has insured that the chick will stay with the parent under the most adverse conditions, a similar mechanism must operate with the child, who obviously could not survive alone.

In fact, that most modern societies have made provisions to give children adequate physical care may obscure the functioning of a mechanism that binds the child to the parent during his period of dependency, even when physically punished. However, as Polt suggests, it seems as though the normal parent-child relationship implicitly assumes that something of this sort operates. When a parent physically punishes a child for some misdemeanor, the purpose of the punishment is to deter the child from repeating the act with which the punishment is associated, not to lead the child to avoidance of the parent. If the normal association-learning laws were operative in the situation, the parent would be the object most closely associated with the punishment, and avoidance of the parent, rather than deterrence of the child from continuing the misdemeanor, would result.

Development of social behavior. The basic imprinting phenomenon implies that in a number of species there is a specific time in the development of the animal when it is most susceptible to the formation of primary social bonds with fellow species members and that this period usually occurs quite early in the life of the animal. In addition to adding a certain degree of substance to Freud's theory of developmental periods early in the life of the human child, imprinting research has served to reinforce and, in some cases, generate studies, such as those done by Spitz in 1945 and Goldfarb in 1943, that indicate the effects early institutionalization can have on later behavior. Very clearly, the environment of the human infant must satisfy certain minimal requirements during the 1st year of life if he is to show the psychological devel-

opment required or expected by the society in which he is living.

One of the strongest supporters of ethological concepts as applied to the development of social behavior in humans has been Bowlby, who has viewed smiling in the human infant as an instinctive behavior pattern and who has drawn certain analogies between imprinting and the human mother-child relationship.

In outlining the similarity between smiling in the infant and innate behavior patterns found at the animal level, Bowlby presents the hypothesis that the smiling response increases the infant's chances of survival since it makes the infant more appealing to the mother. He further suggests that there is a possibility that in the evolutionary history of man there has been a selection factor favoring this response and that infants without this response had a much higher mortality rate. Besides, there is a specific stimulus that elicits smiling in the infant—the schema of the human face—and this can be considered a releasing stimulus in the ethological sense. And the smiling response is said to be stereotyped and will occur in all members of the species. Ambrose, an associate of Bowlby's, points out that there also seems to be a critical period for early smiling, which is terminated by wariness of strangers, very much like the fear of strange objects that cuts off following in an imprinting situation. This application of ethology to human development has led Bowlby to conclude that other instinctive behaviors may also exist at the human level.

Perhaps of greater importance to psychoanalytic theories of the development of personality is the idea that clinging and following in the human infant are instinctive behaviors. This also has been outlined by Bowlby. It is his contention that, when the child is capable of locomotion, his following of the mother or mother object is like imprinting in other animals and that certain irrevocable bonds are formed through this behavior. On the basis of his observation and treatment of disturbed children, Bowlby has concluded that there is a high degree of correlation between emotional problems in childhood and complete lack of a mother object or lack of one that permits sufficient exercise of the child's responses of clinging and following.

The research on imprinting and the effects of early experience that has been carried out in a rather massive fashion with a variety of animals from the lower vertebrates to birds, mammals, and even primates has added substantially to an ethological approach to the problem of such bond formation, even at the human level. This research suggests the possible effects of an inadequate relationship and inadequate exercising of certain abilities.

Pupillary changes. Another area of research that has recently been developed in psychology uses some of the basic techniques of ethology and may prove to be of value to the psychiatrist. First reported in 1960 by Hess and Polt, this technique bypasses verbal

questioning of a human subject and relies on changes in pupil size as the subject reacts to stimulation. Briefly, Hess and Polt found that subjects looking at pleasing or interesting visual material had enlargement of the pupil. Looking at neutral material, there was no change. Looking at pictures that were distasteful in some fashion caused contraction of the pupil. The amount of brightness of visual stimulation was, of course, controlled. Just as the ethologist depends on his knowledge of the behavior of a species under normal conditions to judge what is not normal in the behavior, this technique uses observation of the pupil of the eye to determine what might be called the mental behavior of the person under observation.

Conclusion

The contribution already made by ethology to psychiatry is only a beginning compared to its potential. Thus far, ethology can be said to have contributed in three ways. First, it has given rise to concepts, such as displacement activity and fixed-action patterns, that have been taken up by psychiatrists and used in their interpretation of normal and aberrant human behavior. Second, a large body of experimental data has been accumulated in regard to effects of early experience and imprinting, and it has been possible to draw parallels to human behavior and, in at least some respects, to test the hypothesis generated from the animal work in relation to how they fit human early behavior. Third, the methods and techniques of ethology can be and to a degree already have been used in psychiatry. Knowledge of normal behavior and normal development of behavior are cases in point. The use of schematic representations to determine whether or not sign stimuli or releasers are operating at the human level, as in the case of the smiling response to schematic representations of the human face, allows us to come to grips with certain aspects of early human behavior. And the use of techniques that do not involve verbal responses, such as the pupil phenomenon technique described previously, may allow us to gain information about the development of attitudes and perceptions in the infant and developing child, either before verbal responses are possible or where verbal responses may, perhaps, not be trusted.

There is one great over-all value that ethology and what might be called ethological psychology can bring to psychiatry. This is the rediscovery that man is a biological organism, that man must have a background and bring to present day species members an ancient repertoire of behaviors that have some bearing on the problem of human behavior today. From the ethological point of view, the human infant is not a completely naive, innocent being. He has a legacy of potential behavior patterns that at one time assured the survival of the organism. Some of these innate behavior patterns must assuredly involve sexual behavior, aggressive behavior, and innate social responses. The realization that these potentials are present and that

much of these potential behavior patterns must be channelled into quite different directions in our present day civilized world may make a great contribution to an approach to the problems of man and could have a tremendous impact on the search for mental health. To assume, for example, that aggression is somehow the result of bad aspects and environment is to close one's eyes to the evolutionary usefulness and biological survival value of aggression, which surely must have a place in the makeup of man, as it does in all other organisms. If, in this one case alone, aggression were recognized as a normal and useful biological consequence, ethology would have made a major contribution to the field of psychiatry.

Suggested Cross References

For a more detailed discussion of the principles of learning, see Bachrach's section on learning theory (Section 3.3) in this chapter. Psychoanalytic theory, which is mentioned in this section, is described more fully in Chapter 6 on classical psychoanalysis by Mack and Semrad in Area C, on current theories of personality and psychopathology. Section 38.2 on child development by Eisenberg and Section 44.1 on maternal deprivation by Yarrow in the child psychiatry area (Area H) deal more fully with the subject of development of human behavior.

3.6 SOCIAL COMMUNICATION

JURGEN RUESCH, M.D.

During the 19th century, physiologists talked about system-functions such as circulation, respiration, and digestion. The more behavior-oriented physiologists and psychologists added such considerations as locomotion, perception, expression, and motivation. Psychiatrists were mostly concerned with aberrations of thinking, feeling, and action. Anthropologists constructed cultural typologies. The linguists studied language codes. And the sociologists analyzed social structure. The tendency of scientific research was to study progressively smaller areas of structure and function. But, as Kety stated, "We do not always get closer to the truth as we slice and homogenize and isolate—that which we gain in precision and in the rigorous control of variables we sometimes lose in relevance to normal function, and . . . in the case of certain diseases or problems, the fundamental process may often be lost in the cutting."

The 20th century departure from the older scientific procedures of slicing structure and function into progressively smaller parts can be traced in the field of communication to the introduction of the concept of steersmanship or cybernetics, which, based on the notion of feedback, enabled engineers to integrate part functions into a whole. The advances made in the field of communication engineering soon spread to the field of human behavior, with the result that scientists no longer confined themselves to the study of single human beings in isolation from one another. The emphasis switched from the person to the message, making it possible to trace communications as they pass from one individual to the other through institutions and machines, to their ultimate destination in another person.

Communication can be defined as the process that links discontinuous parts of the living world to one another. It is made possible by three basic properties of living organisms found at all levels of organization, from the single cell to complex societies. In or-

ganisms, these properties are called perception, evaluation, and expression; in research, they are sometimes referred to as input, decision making, and output. In spite of the fact that these functions constitute an organizing principle of nature, there does not exist as yet a unified theory of communication. Instead, each discipline has developed its own theoretical position. A brief survey of the various approaches to communication is presented in Table I.

Basic Social Process

When individuals communicate with each other, they engage in a social process that is controlled by three sets of determinants. The organs of communication (sensory system, effector system, and central nervous system) and the urge to use these organs are part of the individual's genetic endowment. The environment to which a person is exposed and the people by whom he is surrounded represent the social determinants. And the manner in which his experience influences his knowledge, his skills, and his ways of adaptation can be considered the psychological determinants. Thus, communicative behavior is influenced by biological, social, and psychological factors.

When all these complex and interwoven patterns are reduced to a few fundamental premises, we arrive at a description originally formulated by Cantril, who stated that man requires the satisfaction of his survival needs and seeks security in a physical and psychological sense; he craves sufficient order and certainty in his life to enable him to judge with fair accuracy what will or will not occur; he seeks to enlarge the range and to enrich the quality of his satisfactions; and, being a creature of hope, he is not inclined to resign himself easily. Since man has the capacity to make choices, he desires freedom to exercise this capacity. He wants to experience a sense of his own worthwhileness, and he wants to share a system of values or beliefs to which he can commit himself. Also, he needs to live in a society that holds out a fair degree of hope that his aspirations will be fulfilled.

In implementing these needs and in seeking to realize his potentialities, man engages in a social process that can be described as follows.

Man is a herd animal, and distinct or prolonged separation from the group is frustrating to him. Therefore, every individual strives to prevent separation from the group at the same time that he attempts to remain a distinctly separate entity within the group. The individual achieves this balance by controlling the type and magnitude of social differences that exist between himself and others.

Excessive differences that may produce tensions can be decreased (1) through equal exposure of people to things, persons, and situations (similar experience); (2) through social interaction, thereby establishing correspondence of information and behavior (communicative exchange); (3) through shared explanations to justify existing differences (interpretation);

TABLE I
Approaches to Communication^a

Discipline	Field of Specialization	Source
History		
History of language	Development of language over the centuries	Hoselitz, Pei, Revesz
History of communication engineering	Development of communication technology and codes	Cherry
Theoretical disciplines		
Cybernetics	Steersmanship and feedback in biological and social systems	Wiener
Mathematical theory of communication	Information theory	Shannon and Weaver, Brillouin, Pierce
Communication engineering	Computers, automata, and control devices	George, Latil, Licklider
Scientific philosophy	Assumptions made in scientific procedures	International Encyclopedia of Unified Science, Ruesch and Bateson, Horowitz
Unified theory	Communication as general systems theory	Ashby, Bertalanffy
Behavioral sciences		
Neurophysiology	Communication and the central nervous system	Horrobin; MacKay; Miller, Galanter, and Pribram; Rosenblith
Neuropsychology	Perception, transmission, decision making, memory	Broadbent, Churchman, G. A. Miller, J. G. Miller
Ethology	Animal communication	Sebeok, Hess
Social sciences		
Social organization	The organization of social networks	Argyris, Kahn
Group process	Communication in small groups	Collins and Guetzkow, Homans
Mass media	Television, radio, press	Dexter and White, Klapper, Schramm
Language and codes		
Linguistics	Phonetics, language codes	Saporta, Osgood and Sebeok
Significs	The meaning of signs and signals	Berelson, Morris
Symbolic systems	Verbal and nonverbal codes	Hall, Skinner, Whorf
Biological codes	Genetic code	Beadle
Commercial disciplines		
Propaganda and advertising	Influencing people to act	Packard
Political thought reform	Influencing people to believe	Lifton, Hinkle and Wolff, Schein
Business organization	Efficiency of communication	Redfield, Haney, Haire
Clinical disciplines		
Family psychiatry	Communication difficulties inside the family	Ackerman, Bell, Howells
Individual psychiatry	Disturbed communication	Bateson, Jackson, Haley, and Weakland; Ruesch
Group therapy	Group analysis	Foulkes, Slavson
Psychoanalysis and psychotherapy	Communication with patients	Feldman, Haley, Meerloo, Ruesch
Mental hygiene	Community organization	Bellak, Duhl, Leighton
Neurology and neurosurgery	Pathology of organs of communication	A.R.N.M.D. Proceedings (1962), Pribram
Psychopharmacology	Influence of drugs upon communication	Kalinowsky and Hoch, Sargant and Slater
Speech disorders	Aphasia, reading disability	Brain, Hermann
The arts		
Painting and sculpture, dance, theatre, music	Expression of inner events through shape, color, movement, texture, and sound, resulting in the creation of nonverbal signals and signs to which others respond	Gombrich, Ostwald, Stanislavsky
Arts and crafts		
Architecture, decorative arts, cabinet making, handicrafts, interior decoration, fashion design	Shaping of the material environment embodies the assumptions and conventions of a particular period and person. Architectural structures and objects may become symbols for communicative exchange of people with each other and with posterity	Gorsline, Hall, Hogben, Larousse Encyclopedia of Mythology, Ruesch and Kees, Laver
Social games		
Law, politics, sports, special social situations	Stylized message exchange by participants who assume certain roles and abide by well established rules can be analyzed as if it were a game or a play	Berne, Neiman and Hughes, Jackson, Sarbin

^a For the pertinent works by the authors listed in the third column of this table, the reader is referred to the reference section at the end of this article. Complete bibliographic references for the sources cited may be found in other publications of the author.

and (4) through coercive action or threat of coercive action in case of deviance (social exclusion, imprisonment, hospitalization).

Insufficient differences may also produce tensions. Differences between people can be increased (1) through isolation from the group and exposure to self (solitude); (2) through exposure to new groups (culture change); (3) through the acquisition of knowledge or skill not possessed by others (achievement); and (4) through unusual life experiences not shared by others (illness, adversity, adventure).

If a balance cannot be achieved between personal identity and group membership, the ensuing tension usually exerts a disruptive influence on both individuals and group. This tension can be reduced to a tolerable level if one or more persons adapt pathologically, in neglect of their own needs, or if the disruption of the group leads to new group formations.

Assessment of Social Networks

The social process that connects person with person, or the social conflict that disrupts relationships, can be studied best through observation of the ways and means of message exchange. The following questions may serve as a guideline in the assessment of groups: Who? (status, role, identity); said What? (content); to Whom? (status, role, identity); When? (chronological, biological, elapsed time); Where? (situation); How? (codes); with what Effect? (feedback).

The questions *who* and *to whom* must be answered in terms of role, status, and identity. Out of a pool of thousands of people, the persons who actually sent and received a given message must be selected. The clues here may be found not only in the social characteristics of the sender but also in the message itself. The manner in which a communiqué is coded, phrased, and timed frequently identifies the sender, a fact used in detective and intelligence work. These explanatory or instructional aspects, which help in deciphering the main content of a message, have been referred to as the metacommunicative aspects of communication. For example, a certain signal given by a uniformed traffic officer is a command; the same signal given by a 10-year-old child may be interpreted as play. Or a poorly constructed letter containing errors in grammar and orthography may be assumed to have been written by a person with relatively little education.

The *what* of a communication refers to the events that signs and symbols stand for. Proper usage presupposes the existence of a dictionary or legend. Unfortunately, people use, in addition to the standard dictionary, a multitude of other informal and usually unprinted "dictionaries." Mothers and babies, husbands and wives, industrial and work crews, and sports teams develop private vocabularies. Thus, a message can be interpreted in many ways, according to which legend is used. The study of the broad conventions that regulate this process of attributing

meaning is the domain of cultural anthropologists. The narrower conventions are studied by language experts and psychologists. And in the case of patients and their relatives, the psychiatrist and the psychoanalyst are the professionals who specialize in deciphering idiosyncratic and particularistic language.

The *when* of a message refers to different aspects of time and timing. Clues must be found which indicate the historical period, the point in the development of the situation, the age of the participants, and the nature of other messages that preceded or followed the message under study.

The *where* of a message deals with the social context in which the communication takes place. The situation or occasion (wedding, traffic accident, lunch) usually furnishes a label that enables the participants to identify the pertinent rules. These, in brief, indicate who can talk to whom, about what, for how long, where, and in what manner—and the consequences if the rules are violated.

The *how* of a message refers to the code in which it is phrased. In the exploration of this area of communication, speech and language experts are joined by the gesture experts and all those other artists and craftsmen who specialize in nonverbal codes. In addition to written languages, there exist many auditory and visual codes, such as semaphore, Morse code, jungle drums, and the sign languages of the Indians and of the deaf and dumb.

The *effect* of a communication can be evaluated by studying the change it produces. An initial statement by one person or group is usually followed by a reaction on the part of another person or group. During the exchange, the identity of the participants, the schemes for interpretation, the rules of procedure, and the referential properties of the symbols are clarified. A message may be said to have had an effect if it has changed the parameters of the system. The chances of relating subsequent effects to the information contained in a given message are better if the interval between message and reaction is short. If the interval is long, intervening factors blur the cause and effect relationship. Large scale evaluations of effects are undertaken by advertisers, propagandists, government agencies, and public health experts.

Disturbed Communication

Disturbances of communication arise when messages are too intense, are perceived in a distorted way or not at all, arrive too early or too late, or are inappropriate to the situation. The therapeutic measures vary with the circumstances under which the disorders occur and the ways in which they affect the participants.

Disease, trauma, or malformation of the organs of communication may lead to distortions of perception, evaluation, and expression. In such conditions, the therapeutic intervention is predominantly somatic.

Perception, evaluation and expression may be quantitatively altered because of overload or underload, incorrect timing, and other factors subsumed under the term "stress." Here the therapeutic intervention is designed to program the individual in such a way that he no longer exposes himself to stress. Sometimes large scale social reorganization may reduce human stress.

Perception, evaluation, and expression may be qualitatively distorted in that these functions do not provide for correct information or response. Because of one-sided experience or lack of social skills, a person may be ill prepared to communicate in the setting in which he finds himself. Therapeutic intervention here is directed at reeducation or at helping the person find a more suitable environment.

The communicative process may be distorted because actual or imagined content is threatening to the participants. In this case, the therapeutic intervention is directed at the correction of erroneous perceptions and evaluations or at helping the patient accept circumstances that cannot be altered.

Communication may be disturbed if feedback processes are not functioning properly. Lack of acknowledgement, delayed response, replies that are not relevant to the original statement, and failure to reach agreements may all exert a disorganizing effect on both individual and group. Also, if the participants have an erroneous model of what is going on, they cannot behave appropriately. In dealing with distorted images of reality, the most significant therapeutic measure consists of exposing and discussing the unrealistic assumptions. If the processes that stabilize distortions have been rendered inoperative and corrective feedback has become rewarding, a more realistic image of the world is likely to develop.

Therapies Based on Communication

Once the presence of disordered communication has been established the psychiatrist must decide what type of intervention is appropriate in order to restore functioning. The psychiatrist may influence his patients by intervening with the human instruments of communication, as in psychosurgery, electroshock, and drug therapy. He may attempt to change the patient's body of information by means of the psychological therapies. Or he may try to alter the ways of responding, as in the social therapies, either through direct retraining or through changes brought about in the environment or in the relationship between the patient and the environment. These interventions may all be conceived of as being based on two central features, communication and organization.

As a therapeutic tool, communication may be used to help the individual increase his awareness of himself and of the ways he fits into the existing social and cultural patterns, acquire communicative skills and the ability to get along with people, abandon unnecessary assumptions that restrict effectiveness, and

modify his attitudes in the direction of understanding and tolerance of behavioral differences.

Within the small group, communication is used to clarify the roles of the participants, to specify the rules that the group observes, to verbalize the assumptions of the various participants, and to formulate goals of action acceptable to all.

Reorganization of the social system that surrounds individuals may consist of (1) introduction of new organizational structures or removal of obsolete ones (agencies, committees, associations, laws, and regulations can be created to take care of social needs as they arise; this is a task of social planning); (2) alteration of existing networks of communication (the flow of messages, the place of decision making, the organization of checks and balances can be changed; this is a task of management); and (3) adaptation of technological procedures to fit the needs of individuals (treatment methods can be adapted to blend with the political, economic, and ethnic values and practices of the local population).

In practice, the therapies aimed at improving the social communication of people are known under a number of different names.

The term community psychiatry refers to a complicated set of operations aimed at changing the attitudes and tolerance limits of a given group to insure the best treatment of their sick members. Once this goal has been achieved psychiatric treatment methods and procedures can be adapted to that particular community (rural, metropolitan, military, industrial, academic, etc.), and the necessary resources and facilities can be mobilized.

The term therapeutic community refers to carefully managed relationships between patients and staff in an institutional setting, whereby the patients have time limited and often controlled contact with the area and the people surrounding the hospital.

Group therapy, group psychotherapy, analytic group psychotherapy, and psychodrama all utilize the group setting for therapeutic purposes. Depending on the particular method chosen, the main efforts are directed toward guidance, counseling, lecturing, inspiration and exhortation, activity and play, or the acquisition of insight.

Family therapy involves the treatment of an entire family by the same therapist or by different therapists. The family members may be seen interacting with each other in the presence of the psychiatrist or the therapeutic team, or they may be seen separately.

Occupational therapy and work, play, music, drama, or dance therapy are oriented toward skilled activities, and human interaction is subordinated to the physical task at hand.

Social programing refers to the discussion of specific social tasks individually or in groups. The technical aspects of how to get a job, how to behave at a social gathering, or what side effects to watch for when tak-

ing medications can be reduced by step-by-step operations and taught to the patient and his relatives.

Regardless of whether the psychiatrist deals with organization, somatic therapies, psychotherapy, or group therapy, he has to deal with people. He relies on the built-in desire of the individual to seek human contact, and he gains leverage and exerts his influence through three fundamental processes: understanding, acknowledging, and agreeing. Understanding involves the establishment in the mind of the therapist of an accurate model of the patient's behavior; to be understood is a rather pleasant experience for the patient. Acknowledging refers to the therapist's receipt of the patient's purposive or involuntary messages; to be acknowledged is even more gratifying for the patient. Agreeing implies the isolation of a certain aspect within the universe of discourse and the establishment of corresponding views or bodies of information regarding this aspect; to reach an agreement is most satisfying.

Communication Engineering as an Aid to the Psychiatrist

The phenomenal advances made in communication engineering have left their mark on psychiatry. The psychiatrist's functions of perception, scanning, memory, computation, reasoning, decision making, expression, and action can be vastly expanded through the use of communication technology. Mass education and perhaps even mass treatment will become more significant as further technological advances are made. Some of the applications of communication engineering that may affect the work of the psychiatrist have been sketched in the following paragraphs.

Computers

Information storage and retrieval. Procedures are now available for storing the information contained, for example, in books or periodicals. Any page in such a collection could be located in a fraction of a second. It is possible that in the future computer storage and retrieval of information will be cheaper than the present system of libraries.

Computation and statistics. Complicated mathematical operations that would take human beings years to work out can be solved in seconds. Budget computations, logistics, and other administrative tasks are greatly facilitated by computers.

Data processing, decision making, and problem solving. Computers can scan, translate, combine data, and perform many other functions of the human mind. As aids in decision making, they can weight factors properly and can consider more material in a shorter period of time than the human brain can. For example, results of blood, urine, spinal fluid, x-ray, and other examinations can be quickly combined to yield a medical diagnosis. Similar procedures can probably be used

for the assessment of personality as better measurements of behavior become available.

Computers as scientific models. Computers can be used as models of organisms or society. The program for a computer that reenacts a process is becoming just as acceptable a theory of that process as the equation describing it. With such a procedure, more precise definition of various functions can be achieved than has been possible up to now. Reenactment or simulation of natural phenomena is the path on which scientific advances are currently made.

Programmed instruction

Texts. Textbooks can now be written in very much the same way that teaching machines operate. A question is presented, and if the student answers it correctly he proceeds to the next one. However, if he answers incorrectly he is advised to do more studying on that specific point.

Mechanical teaching machines. In a variety of semiadaptive teaching machines that are operated by hand or electrically, questions and answers are presented serially. The next question is not revealed if the previous one has been answered incorrectly. This forces the student to find the correct answer if he wishes to continue.

Computerized teaching programs. A computer can present questions to a student by way of television or on a typewriter. The student then types out his answers, and this serves as input to the computer. If the answer is wrong, the computer gives the student more training on the spot. If the answer is correct, the computer presents the next question. Such computerized programs can be used with a variety of psychiatric patients, for example, the mentally retarded, the brain-diseased, or the emotionally disturbed slow learner.

Therapy machines. With automatic control devices, suitable machines can carry out tasks formerly performed by people. Psychiatry has made little use of this aspect of technology, but in the future it should be possible to program computers to interact with patients or to rehearse certain behavioral features with which the patients have difficulty. For example, a patient can be given an opportunity to learn and abreact at his own speed; and if he is slow and redundant the machine has more forbearance than the human being.

Mass media

Broadcast television, closed circuit television, and radio. These media facilitate the delivery of lectures at any time, practically anywhere. Taped lectures can be preserved, evaluated, and sold, and for this reason they are generally more carefully prepared. The mass media approach is particularly significant in teaching students, training personnel, addressing relatives of patients, or informing boards of

hospitals or public health agencies of current trends and needs in psychiatry.

Perception and action by remote control

Microphones and television cameras can now be placed in difficult locations that formerly were not accessible to observation, e.g., inside an organism or amidst a social group. Recording observations in this way obviates the presence of the scientist. The observations can be preserved over time, and all the scientist has to do is evaluate the tapes. Psychiatrists use closed circuit television to monitor two-person and larger group sessions. With this method also the psychiatrist or the patient can be confronted with his own behavior, which he may never have seen or heard.

In the technological age the psychiatrist will progressively make more use of modern communication machines in teaching, research, and treatment. And in all probability the future training of the psychiatrist will include some aspects of communication engineering.

Suggested Cross References

In this section human behavior and psychiatric treatment were discussed from the viewpoint of communication theory. Alternate hypotheses regarding human motivation and personality are presented in Area C, which deals with current concepts of personality and psychotherapy. For discussions of psychiatric treatment procedures that are based on different conceptual models, see Area G, on psychiatric treatment. More detailed discussions of the many aspects of psychiatry to which communication theory may be applied are found in the sections dealing with community psychiatry,

milieu therapy, group and family therapy, and occupational therapy.

Chapter 4

Basic Sociocultural Sciences

4.1 ANTHROPOLOGY AND PSYCHIATRY

ANTHONY F. C. WALLACE, PH.D.

What is recognized as pathological in behavior is usually a matter of common consensus within a society. But the standards of consensus vary from one society to another. In the United States, for instance, hallucinatory experience is generally regarded as *prima facie* evidence of at least temporary mental disorder. But in many primitive tribes hallucination is not regarded as evidence of pathology at all; rather, it is an experience deliberately sought and prized for its presumed value as a communication from supernatural beings. The anthropologist, who studies human societies in an evolutionary and cross-cultural perspective, explains such differences as the results of differences in culture.

Culture, in the anthropologist's sense, is the sum of what the individual members of a community—be it a small band of hunters or a large industrial nation—have learned from generations of accumulated social experience. It includes manners, customs, tastes, skills, language, beliefs, and all the other patterns of behavior that are part of organized social life. Just as cultures differ in technology, kinship practices, and religious belief, so they differ in the behaviors classified as normal and abnormal.

History of Psychoanalytic Anthropology

The involvement of anthropology with studies of personality and psychopathology began in earnest with the efforts of psychoanalysts to apply their insights to cultural data. This tradition in Freud's own work is best known in *Totem and Taboo*, *Moses and Monotheism*, and *The Future of an Illusion*. Psychoanalytic anthropology has been developed and refined by a number of later scholars who combined anthropological training and field work, particularly Geza Roheim, Weston LaBarre, Abram Kardiner, and George Devereux.

The main stream of the culture and personality

studies, however, springs from a combination of the American ethnographic tradition, as developed by Franz Boas and his students, and a variety of psychological and psychiatric traditions, of which psychoanalysis is only one. Margaret Mead and Ruth Benedict, both students of Boas, are perhaps the best known representatives of this eclectic and humanistic tradition. In this tradition, psychological insights from a variety of sources infuse and illuminate ethnographic description.

A more systematic approach relies on tests, measurements, and formal models of analysis of values, communication processes, personality structure, and psychopathology. This approach is found in the work of Hallowell, Kluckhohn, Whiting, Spindler, Bateson, Opler, and Wallace. But many of the most significant contributions have been made by anthropologists who are not primarily identified with culture and personality. For instance, Malinowski's analysis of the important role of the mother's brother in many primitive societies suggested modification of the simpler forms of the Oedipus formulation. The work of anthropologists in these areas has been collected or reviewed by Honigmann, Kluckhohn, Murray, Schneider, Barnouw, Hsu, and Kaplan.

Correlations within a Culture

Cultural anthropologists have worked from intensive case studies of individual cultures and from statistical cross-cultural studies to explore the degree to which various aspects of culture are correlated. These studies show that change in any one sector of culture, for instance, in technology or economic system, is apt to produce a series of changes in other sectors, such as family structure, religious belief, and values. The studies also show that certain assortments of culture elements are more congenial than others and are most likely to be found together in a society; for instance, strong belief in witchcraft tends to occur in societies with poorly developed governmental systems of social control.

The statistical associations in such findings are not impressively high. However, the implication for psychiatry is that the folk definition of behavior disorder

der; the precise symptoms of that disorder; the stresses contributory to its development, onset, and course; and the methods of social response to the disorder are likely to be more or less direct functions of many cultural factors such as economic system, family structure, political organization, and religious belief and practice.

Several generalizations can be made about behavior in cultures. (1) There are always folk criteria for distinguishing behavior that is normal from that which is abnormal. (2) Abnormal (as distinct from merely wrong or criminal or even pathological) behavior is always explained as a result of interference, by disease or by supernatural agencies, with the normal functioning of the organism. (3) Conventional therapeutic or extrusive procedures are always available and believed to be effective to end any unwanted interference and thereby to restore the victim's behavior to normal, or at least to minimize its disrupting effect on the community. (4) There are no human societies in which mental disorders, of one sort or another, never occur. (5) In most human societies, both primitive and civilized, both Western and non-Western, the same major symptom clusters can be recognized: schizophrenias, depressions, conversion reactions, dissociative reactions, obsessions and compulsions, phobias, and psychosomatic ailments.

Similarities of Psychotic Processes

Despite the difficulty of securing adequate statistical data, societies do seem to differ markedly in preferred style of symptoms, in the incidence and prevalence of major types of disorder, and slightly, in total psychiatric census. Furthermore, societies exotic to Western eyes may display dramatically different "ethnic psychoses," whose symptoms may, at first glance, appear strange to Western eyes: *amok* in southeast Asia (a homicidal rampage), *latah* in Malaya (echopraxia), *piblokto* among the polar Eskimos (an endemic convulsive disorder).

For example, the windigo psychosis, repeatedly described among the Algonkian hunters of northeastern North America, is superficially unique. These people, although recurrently faced by starvation, do not condone cannibalism. The victim of the windigo psychosis, however, gradually becomes convinced that he is possessed by a supernatural monster, the windigo, whose taste for human flesh is notorious in mythology. He himself experiences an increasingly imperious urge to satisfy a cannibalistic appetite. He attempts to control it, to withdraw from tempting contacts with family and friends. Finally, he may attempt suicide or urge others to kill him, lest he actually become a cannibal. Indeed, he may be physically restrained or even killed by a terrified community when they learn of his fears.

However, these unique delusions and occasional accompanying hallucinations appear to follow the same sort of mental process that in Western society may

accompany fears of homosexuality (as in Freud's analysis of the Schreber case) or of heterosexuality (as in the panics among medieval nuns over seduction). In other words, the basic structure of a paranoid process involving fear, defense against the fear, and powerful but disallowed impulses in a progressively delusional set of defense mechanisms is apparent in the supposedly exotic windigo syndrome.

Varieties of Psychotic Causes

Etiologies, in fact, appear to be more diverse than the basic symptomatic structures. The variety of social structures displayed in the archives of ethnography provides a vast spectrum of possible emotional stresses to which individuals may respond with psychopathological behavior. In regard to the household in which the child lives, for instance, there is the Western European ideal model of the nuclear family, in which mother, father, and children live together in an apartment or house of their own. There are also polygynous societies in which each child lives with his mother and siblings, and the husband and father only occasionally, or never, spends the night with his wife and their offspring. There are societies in which a number of nuclear families live under the same roof, the affiliating genealogical connection being sometimes matrilineal, sometimes patrilineal. There are societies in which a woman has several husbands. There are societies in which the mother's brother plays some of the roles played by the natural father in our own culture. There are societies in which the infant is cared for by a large number of mature females. The list could go on and on. The patterns of identification, love, and hate that are most likely to arise in these different domestic arrangements are diverse.

Even the political structure provides different opportunities for stress and for particular kinds of symptomatic relief. Societies in which there are no political institutions that can maintain social control by invoking effective sanctions against wrongdoers are apt to be rife with fears and accusations of witchcraft. This is less apt to happen in those societies in which the individual can seek protection and legal recourse by appeal to human authority. The fear of witchcraft as a cause of illness or even death functions in politically weak communities as a principal deterrent to interpersonal aggression.

Religious beliefs, too, are notoriously variable from culture to culture. They condone, reward, or taboo human impulses in a remarkably irregular way.

National Character

Many observers, both anthropologists and psychiatrists, have suggested that each culture is associated with a common, or at least widely shared, national character (or basic or modal personality structure). This character is particularly adapted to the prevailing social structure and belief system and is, at the same time, particularly vulnerable to certain stresses.

From this point of view, the type of neuroticism (focusing on an Oedipus conflict involving a nuclear family in which the father holds the position of supreme authority and the mother is the nurturant figure) that Freud was able to define as common among his patients is by no means universal. On the contrary, it is specific to a few cultures, including that of central Europe at the end of the 19th century. Even if some sort of triangular libidinal relationship among child, adult male, and adult female is universal in mankind, it is argued that the course of character development and of neurosis will differ from culture to culture. Thus, where the father appears to the child as marginal or ineffectual in comparison with the mother, the growing male may find it difficult to identify with a male figure. The child may, therefore, have to accomplish a male identification by undergoing a dramatic puberty ritual (as among Australian aborigines) or by compulsive display of external symbols of masculinity (as among American Negroes).

In this connection it should be pointed out that large modern states like the United States are polycultural; they display a diversity of socioeconomic classes, geographic regions, and ethnic origins. The psychologist or psychiatrist cannot assume that a single American culture or American personality exists in a sense comparable to *the* culture and *the* national character of a small primitive tribe.

Institutionalized Symptoms

Most societies, even the most complex, have traditional means for accommodating themselves to episodes of disturbed behavior. In a sense, the task of the culture is to institutionalize and channelize the symptoms of an endemic disease in such a way that the symptoms are not disruptive of orderly community life. Such institutionalization minimizes the costs of extruding the sick person from the community by confinement or execution. It also minimizes the cost of maintaining the sick person in the company of his family and associates.

The means of institutionalization seems to be of three kinds: the denial of illness, special roles for the chronically ill, and therapeutic rituals for those (who may number most of the community) whose disturbances are occasional and episodic.

Denial of illness. There is a tendency in our own society for families to ignore or deny even gross symptoms in a member. Although this may be deplored where more effective means of treatment are available, such a procedure at least has the probable advantage of not adding to the sick person's difficulties the burden of being publicly branded as incompetent. Where the condition is widespread, where there is no reliable and inexpensive treatment, and when the symptoms are episodic and not severely threatening to community welfare, such a policy has even more merit.

In our own culture, the ignoring of emotional dis-

orders associated with menstrual periods seems to be dictated by such considerations. Among the Polar Eskimos, *piblokto* (fits of convulsive hysteria whose cause is not fully understood) is apparently treated with a similar indifference. On the other hand, in some other cultures, menstruating women (whether or not they suffer from premenstrual tension) are taboo and physically isolated because of beliefs concerning the dangerous nature of menstrual contamination. And, in our culture, episodic convulsive disorders are often regarded as serious, requiring heroic measures of treatment.

Special roles for the ill. In many societies, including sectors of our own, a person suffering from a chronic condition such as schizophrenia is allowed to take on or is even encouraged to take on the role of shaman. He is regarded as a person who has a special skill in communicating with or manipulating supernatural powers and beings and who performs for a fee such services as divining the location of missing objects, foretelling the future, curing illness, and persuading a divinity to bestow benefits on a client. The shaman's delusions and hallucinations are channeled and institutionalized in a definite pattern of behavior. He secures the support of the community in return for ritual services that the community believes will be helpful. Even in a person who has not undertaken the role of shaman, the occurrence of occasional or repeated hallucinations may give him a recognized role as prophet. His visions and voices are interpreted by the community as communications from the spiritual world. Whatever its impact on public policy or its consequence in the creation of new cults or social movements, the prophetic role has often been an important institutionalized niche for the delusional or hallucinating person in many societies.

Rituals for episodic illness. Religious rituals in almost all societies may give symptomatic relief in episodes of "acting out" to individuals suffering from chronic, but not necessarily grossly disabling, emotional conflicts. In many cultures, rituals are cathartic; impulses that cannot be readily satisfied in the workaday world may find expression in ritual. For instance, in some African Negro societies, voodoo rituals encourage individuals to become possessed by supernatural beings and to act out the variously gratifying roles associated with them. These roles, performed in a dissociated state, permit the dancer to satisfy impulses by temporarily assuming an alternate personality. Rituals under religious sanction may provide occasions for the satisfaction of sexual wishes disallowed under ordinary circumstances, such as incest and adultery. The Iroquois Indians believed that dreams were the language in which the soul expressed its unconscious wishes. They had an elaborate panel of procedures by which frustrated desires could be identified and satisfied.

Not all such rituals are cathartic; they may also be repressive, intended to strengthen the capacity of

the individual to reduce the anxiety of conflict by supporting defense mechanisms. For instance, rituals in which a scapegoat is condemned and destroyed have the effect of enabling the conflict-ridden person to say, "It is not I, but he, who is guilty of such and such wishes." Rituals of confession and absolution similarly permit the individual to feel, temporarily, at least, that guilt has been removed.

Therapeutic and Prophylactic Rituals

The line is thin between rituals intended generally to provide symptomatic relief for any and all members of a community who wish to take advantage of them and those rituals aimed at therapy and prevention for particular persons or classes of persons.

Therapeutic procedures. Specific treatment of mental disturbance in primitive societies very commonly involves one of four principles: exorcising a possessing spirit, recalling the victim's wandering soul, making reparations for the violation of taboo, or countering the spell cast by witchcraft.

The ritual procedures by which the shaman or the group undertake such a therapeutic task may indeed be based on a faulty conception of the nature and causes of mental illness, but such procedures are not necessarily inefficacious. Sharing a belief system with the shaman that defines his ritual as effective, the victim is apt to be relieved of the fear that his case is hopeless and must end in death or the destruction of his identity. Indeed, as Cannon has pointed out, this fear may itself be lethal if the physiological stress accompanying it is not relieved. Furthermore, some shamans interview the patient in order to discover the nature of the taboo violation or the possible occasion for witchcraft. In the interview, the shaman may directly encounter the patient's unconscious conflicts, help him to verbalize them, and thus, in the manner of any good psychotherapist, bring them into a state of consciousness, where the ego can begin to deal with them. To the extent that he is able to do this, the shaman may be able to accomplish real psychotherapy.

Gillin, for instance, describes a Maya Indian shaman in Guatemala who was treating a woman for presumably hysterical conversion symptoms. The native theory of the disease (*susto*) was soul loss, and the ritual treatment was arbitrary and, in a sense, irrelevant to the psychodynamics of the case. However, the shaman did spend a good deal of time talking with the patient in order to find out what emotional shock had frightened her soul away. This discourse rapidly converged on a discussion of precisely those matters a trained psychotherapist would have been attentive to: her unhappiness with an unfaithful husband; her poverty; her memories of her father, whom she loved.

Prophylactic rituals. In what may be called preventive psychotherapy, most primitive societies tend to rely on what are called rites of passage. These are the rituals, often supported by more or less elaborate

religious beliefs, in which a person is separated from an earlier social role and introduced to a new one. They are performed on occasions of life crisis: birth, puberty, marriage, military undertakings, bereavement, and so on. The particular pattern of occasions selected for ritual treatment and the content of the rituals vary, of course, with the culture.

Puberty ceremonies. The rites of passage most relevant to the interests of modern psychiatry are the puberty ceremonies performed on youths and girls, usually in the early stages of puberty, to mark the transition from childhood to adolescence or even adulthood. What is involved is usually more than a mere celebration of the change in social role. In the classic instances, such as the initiation rituals of the Australian aborigines and the bush schools of West Africa, a class of initiates, particularly males, is physically removed from the community and imprisoned in a special compound. There they are instructed in the secrets of manhood and are subjected for days or weeks to prolonged and various forms of hazing at the hands of elder males. The climax of the ritual is the public occasion on which genital mutilation—generally circumcision but among some Australian aborigines subincision also—is performed on the youth. This marks the completion of the process of transformation. The child is considered to have died, to have been reconceived and held in embryonic isolation, and finally, to have been reborn a man. Comparable ceremonies are, more rarely, also conducted for girls.

The unconscious meanings of the acts performed in such rituals are subject to multiple interpretations. The Australian circumcision and subincision ritual has been interpreted as a symbolic castration by jealous elders of young males who potentially compete for their women. It has also been interpreted as the satisfaction of an unconscious womb envy on the part of the males, who by the operation of subincision acquire the simulacrum of a vagina.

Functions of rituals. Every society has communal rituals when a major transformation of role in that society's terms is required of an individual or a class of individuals. It is a reasonable inference that a major function of such rituals is to minimize the duration and depth of internal psychic conflict accompanying major changes in social role by taking the matter out of the individual's hands and, as it were, ritually brainwashing him.

For instance, the primary function of the puberty rituals described above is to facilitate the transformation of children into adults by separating them physically from the parental household, encouraging appropriate changes in knowledge and motivation by a combination of stress and suggestion, and reintroducing them to the community in a new role. The community is expected to respond in complementary fashion. Just as it is obligatory for the child to forsake childish things and behave as an adult, so the adults

of the community are enjoined to respond to the initiate as an adult and no longer a child.

The agonizing conflicts concerning roles, values, motives, and responses commonly observed in many members of Western societies at times of life crisis seem to be, in part, a consequence of the unavailability of *effective* rites of passage. Granted, the price a society has to pay for the advantages of such rites is heavy. They exact a relatively high degree of uniformity. Perhaps the price is too heavy for large, complex societies that are organized for rapid and continuous change in both technology and social structure. If individuality, diversity, and creativeness are prized, then ritualization of psychic maturation may be so costly that it cannot be tolerated. Viewed in these terms, the various individualized psychotherapeutic and counseling techniques developed in industrial societies in the 19th and 20th centuries seem to be the necessary functional alternative to standardized rites of passage. And the continuous outcries against the demands of conformity and the threats to identity imposed by industrial urban society should not be regarded as a sign that modern society is becoming more and more ritualized and uniformitarian. Rather, they are a sign that more and more people are becoming aware that this kind of society cannot function successfully if conformity and uniformity are too highly emphasized.

Studies of Hospitals as Cultural Systems

In recent years, many social scientists, including anthropologists, have studied the social and cultural milieu of the mental hospital. Indeed, a number of psychiatric administrators have encouraged anthropologists to study the social system of the mental hospital, its customs and procedures, and their possible unintended effects on patients. The social scientists have worked on the assumption that the course, symptomatology, and outcome of psychotic and neurotic disorders are heavily influenced by the nature of the hospital environment.

Social conflicts. One result of such studies has been the demonstration of characteristic types of social conflict built into the social system of the hospital staff: the castelike division of the line staff into such hierarchically ranked categories as physician, nurse, attendant, and maintenance personnel, with mobility blocked between categories (a nurse, for example, cannot become a doctor without leaving the organization); the military-like pattern of authority, characterized particularly by the phenomenon of multiple subordination (a nurse, for example, is expected to respond to orders from a number of other nurses and also from physicians, who may or may not be in communication with the nurse supervisors); the tendency for the patient to be so effectively stripped of his outside identity as spouse, parent, worker, and citizen that the reconstruction of a new outside identity or the reassumption of the old one is made very difficult

(even if the patient's psychiatric condition permits it), and he comes instead to display the syndrome of hospitalism (his new identity becomes that of the good, passive, chronic patient).

It is difficult to estimate how much therapeutic benefit would accrue from instituting the changes in hospital organization and practice suggested by such observations. There is no clear understanding of the causes of the functional psychoses or of the relative efficacy of the various therapies available; therefore, the weighting of any one factor must be problematical. But, whatever method of treatment is undertaken, the patient's response must depend partly on his confidence in his physician and the physician's apparatus which in this case is the hospital itself, and partly on what confidence the physician and staff communicate to him.

Communication processes. Anthropologists doing research in psychiatric settings are also interested in the nature of the communication process between patient and staff and between patient and family. For instance, studies have used the techniques of linguistic and kinesic analysis in order to understand better the exchange of feelings and attitudes that goes on below the surface of the content of speech. Such studies tend to confirm clinical impressions that, however indispensable rational conversation may be to the therapeutic process at some points, much of the emotionally significant interchange between therapist and patient (and, for that matter, between healthy individuals) involves the mutual communication of affects by autonomic signs, culturally patterned gestures and postures (kinesic communication), and paralanguage (intonation, voice quality, and so forth). The availability of multiple modes of communication also facilitates those ambiguous and contradictory exchanges described by such terms as the double bind and the identity struggle, which some investigators have regarded as possibly pathogenic.

Alien cultures. The services of anthropology may be useful in clinical settings to evaluate the meaning of the patient's symptoms and his attitudes toward treatment. This is particularly likely where the psychiatrist and other psychiatric personnel are confronting persons from a cultural background alien to their own. To some extent, this may be true even when both patient and staff come from the same country or even the same region or metropolitan area. Marked differences in social class, education, and ethnic background may directly interfere with communication because the staff simply doesn't know what the patient is talking about and may more subtly block agreement on the goals and nature of treatment because the patient's tacit expectations are at variance with the physician's. Segregated ethnic minorities, such as some American Negroes and American Indians, may entertain a world view very different from the middle class psychiatrist's.

This cultural gap is even more obvious where the

psychiatrist is responsible for persons of sharply different cultural background. This may be the case when he is treating visitors from a foreign country or people in underdeveloped areas, such as African tribal societies or United States Trust Territory native populations. Even where there superficially appears to be a familiarity with Western technology and medical belief, certain values, attitudes, and beliefs may baffle the Western physician when he first encounters them in symptom formation or in the therapeutic negotiations. Beliefs about possession, witchcraft, the efficacy of rain-making ceremonies; values concerning the expression of pain, grief, or affection; the obligations of kinship and other social ties; attitudes toward white men and white medicine—all these may be difficult to accept or to interpret. A sensitive and intelligent physician can, of course, learn a great deal from his own patient, from casual association, and from reading the relevant social science literature. But it may sometimes be helpful to consult an anthropologist whose intensive study of the group enables him not only to answer particular queries but to provide a general framework that anticipates future dilemmas. Since anthropologists tend to specialize in particular culture areas, it is necessary to communicate with an expert on the particular group in question.

Evolution of Psychiatric Disorders

One of the traditional contributions of anthropology has been to disabuse modern man, in particular, modern Western man, of various popular ideas about human nature and the evolutionary development of human behavior.

"Happy primitive" misconception. One popular delusion is probably inherited from romantic Rousseauistic notions of the happy primitive. This, in turn, harks back to the ancient doctrine of the Golden, Silver, Bronze, and Iron Ages, with the Golden Age being an era of blissful simplicity, a Garden of Eden, and subsequent ages more and more sophisticated and also more and more evil. In such theories, mental disorder is regarded as a disease of civilization, one that regularly increases in frequency as the civilization progresses. Occasionally, remote tribal populations or isolated utopian communities are cited as places where, because of the uniformly high quality of mother love or the absence of contradictory role expectations or whatnot, functional mental disorders are rare or nonexistent. These psychiatric paradises regularly turn out to be, on closer examination, no more immune to mental disease than other human groups. The inference, of course, is that mental difficulties are not recent afflictions of mankind. They could probably be traced, if records were available, far back in the human phylogeny to a time when technological and social simplicity, comparable to that of modern primitives, was the general condition.

"Sick society" misconception. A related popular misconception is that whole societies can be diagnosed

as suffering from paranoid or other psychoses. This pseudoscientific attitude is apt to flourish most exuberantly when scientists feel the need to condemn their or their nation's enemies without seeming to exhibit unscientific prejudice.

"Inherited neurosis" misconception. In a similar vein, there is little to support the argument that neurotic guilt and the consequent Oedipus neurosis began with some primal parricide (as suggested by Freud) and that the nucleus of the Oedipus conflict is a genetically inherited constant in human nature. There are some startling uniformities in symbolism and mythology across otherwise widely differing cultures. But these can readily be interpreted as the consequences of common features of the human condition, such as prolonged infancy. Or they may be the results of the historical diffusion of culture content. They are far less likely to be the results of inherited modifications of the genetic material. Nor can one support the idea that in neurosis and psychosis the human mind regresses phylogenetically as well as ontogenetically, recapitulating the stages of barbarism and savagery through which our ancestors passed thousands and tens of thousands of years ago.

Vulnerability to emotional conflict seems to be as much a general characteristic of the human central nervous system as its vulnerability to physical and chemical insults. In view of the extraordinary complexity of experience and, therefore, of learning that the human brain is capable of, it is hardly remarkable that so many persons, in all cultures, at one time or another suffer more or less severe episodes of mental disorder. It is more remarkable, indeed, that so few remain chronically ill. There probably are no model cultures that immunize their members against emotional difficulty, either in the present or in the future.

Evolution of social reaction to the mentally ill. What is readily demonstrable is a long term change in the reaction of society to the disordered behavior of those who are mentally ill. Here, a general evolutionary trend is evident.

Hunting and gathering cultures have a work rhythm characterized by periods of days or weeks of intense, exacting effort alternating with similar periods of rest and relaxation. A person's contribution to the welfare of such groups is better measured by what he can do when he is at his best than by how constantly he remains at a standard level of performance. Thus, simple societies can and do tolerate episodic disorders more readily than the more complex societies do. Occasional episodes of hallucination, convulsive seizures, bursts of rage, or depression can be tolerated because the person can be expected to emerge and carry out his role effectively at the next period of intense activity.

Agricultural and, particularly, industrial societies depend far more heavily on continuous, reliable, day-after-day performance of routine tasks, frequently involving intricate machinery and complexly arranged

social relationships. Here, reliability of performance over long periods of time, even at a mediocre level, may be more important than the high peaks of efficiency during occasions of intense effort. The interruption of the routine by episodes of behavioral disorder in such societies may present serious problems and attract therapeutic efforts or sanctions far more intense than in the hunting and gathering societies. In complex societies, therefore, episodic illness is likely to be treated as a chronic problem because the threat it poses is chronic. This is true even where the differentiation of labor and the demand for innovation make uniformity less important as a social value.

Along with this change in the evaluation of episodic disorder, there has occurred the other major change in the response of society to mental disorder. This is the progressive removal of responsibility for prevention and treatment from the religious sphere to the secular sphere, particularly the scientific, medical sphere. So far, medical science has been able to do little more than chip away at the edges of the vast and recalcitrant conglomerate of disorders. Various organic conditions have been discovered that are responsible for behavior disorder. As these are discovered, they are separately classified and treated. But the poorly understood mass of functional neuroses and psychoses—a mysterious amalgam of biological, psychological, and social determinants—still awaits penetration by research. A milestone in cultural evolution will have been reached when valid understanding and quick, effective treatment of mental disorders are achieved.

Suggested Cross References

4.2 SOCIOLOGY AND PSYCHIATRY

IRVING SILVERMAN, Ph.D.

That medicine involves social science as well as biological science is by now a widely accepted idea. The purpose of this section is to relate one of the social sciences, sociology, to one of the medical specialties, psychiatry. The exposition is in three main parts: first, what sociology is and how it fits in among the various social sciences; second, some of the main concepts of sociology and how they may apply to psychiatry; third, three major research projects as examples of empirical studies done at the intersections of sociology and psychiatry.

What Sociology Is

Sociology is an empirical science that studies human relations. Its domain of problems spans two levels of analysis among superorganic (behavioral) systems: the interactional level and the organization level.

The superorganic is the level of symbolic meaning. It is above the organic, the level of life, which, in turn, is above the suborganic, the level of matter and energy. These levels of analysis are logical housekeeping rules for handling concepts so that they may share a common degree of generality at a common level of abstraction. It would violate these rules, for example, to explain a war in terms of molecules or to explain a hurricane in terms of hostility.

Presumably, there are distinct emergent levels of organization in nature that underlie the need for distinct levels of analysis in discourse. But, as tools of analysis, levels are designated for their usefulness—and not without arbitrariness—especially in the division of main levels into subordinate levels (such as those of cell, tissue, and organ within the organic level). For purposes of this section, there are four subordinate superorganic levels: individual, interactional, organizational, and institutional.

Take this as an example of how these levels might emerge: Robinson Crusoe, alone on his island, presents behavior at the individual level. With the appearance of his man Friday, there are situations for behavior at the interactional level. From these interactions emerges a mutual recognition of differences in position—Crusoe as master and Friday as servant; and that is a rudimentary social structure which may be studied organizationally. Insofar as these two organized men come to institute ways of doing things—ways that are learned, shared, and transmittable to others—they could be studied institutionally, that is, culturologically.

Some confusion may exist between common usage and present sociological use of some terms. It is common for a particular place, such as a hospital, to be called an institution. Technically, a particular hospital, such as Bellevue, is an organization; but *the* hospital, that is, the generic idea of such a place as a way of doing things, is an institution—a part of our culture. And culture refers not only to high or highbrow pursuits (such as art, science, and philosophy), but to a society's way of life, including every mundane detail. Moreover, a social organization may be formal, like a school or a government, or it may be informal, like a friendship clique or a society.

The term "system" is familiar enough in such usages as "solar system," "heating system," and "digestive system." The general idea is that of a whole composed of parts (organs) that are interrelated (organized). When we refer to relations among things that we construe as parts of a whole, then we are thinking of that whole as a system.

The distinctive thing about a discipline is its area of problems. For an applied discipline, it is a substantive (content) area. For a basic discipline, such as sociology, it is a conceptual domain of problems. To identify a problem in science, one must have something to explain—taken as problematic—and something to explain it by—taken as given. One must be exempted from explaining the givens; otherwise, one would either go on explaining forever or end up in a circle.

Sociology, then, may be defined as the basic discipline for the study of superorganic systems in which two levels of organization are taken as problematic, that of social interaction and that of social organization. This straddling of at least two levels of problems, a source of manifold confusions, is usual among disciplines in the behavioral sciences. Psychology straddles

the organic and the individual sublevels of the superorganic. Social psychology straddles the individual and the interactional levels. Anthropology, in practice, extends over all levels.

Another source of confusion in the behavioral sciences that is related to the straddling of levels of organization is the duplicity of meanings among concepts. Many a single concept, such as "role," is useful for reference at each level of organization; but at each level, it must be invested with a somewhat different meaning, depending on the system reference that is intended. If the system reference is not clear, the term is ambiguous. Thus the role of mother may characterize the personality of an individual (motherliness) or the nature of an interaction (mothering someone) or a part in a social organization (mother in a family) or a set of cultural norms for a pattern of behavior ("like a mother to me").

Among the social sciences, sociology covers two superorganic sublevels as problematic, social interaction and social organization. The sociologist, of course, may concern himself with the relations between things sociological and many other types of things—individual, cultural, meteorological, etc. But the basic discipline of sociology builds its own distinctive propositions with its own distinctive concepts.

As a presentation device, we shall use some general ideas in introducing and organizing the material. Based on a rough definition of a system—a whole that consists of interrelated parts—the discussion is divided into four main sections. The first two sections focus on the organizational level, first from the standpoint of how the parts maintain the whole, and the second from the standpoint of how the whole maintains the parts. The remaining two sections focus on the level of interaction, on the guidance of each part and on complementarity between parts.

Social Organizations

A system is an instance of orderliness in the universe, a negation of randomness. In studying any system, one may ask, How did such order originate? How is it maintained? Questions of origination may be bypassed here. It is questions on system maintenance, on how a system works and endures, that will be considered. Some of the main concepts in systematic sociology, their meanings, and the ways in which they may be relevant to psychiatry will be explored. Many of the concepts that follow may be viewed as quite general ideas that have been adapted to sociology's particular domain of problems.

Large scale behavioral systems may be vastly complicated affairs of wheels within wheels, within wheels. A social organization, such as the Daughters of the American Revolution or Macy's department store, can do many of the things that a person does in society. It can join organizations, enter into contracts, pay and receive money, etc. These corporate individuals, like an individual person, can operate

with stability and reliability. How is that possible? Insofar as the answer lies within the boundaries of the system itself (apart from its external relations, foundations, or broader context), two analytic perspectives are useful: In what ways do the member parts maintain the system as a whole? In what ways does the whole maintain the parts?

Parts maintain the whole. Insofar as an organizational system "works," each of its parts must, in a patterned way, be somewhere to take its part in a structure, do something as its function, and develop somehow (for example, generate or degenerate) to bring about systemic change. Social systems, then, embody concepts applicable to social structure, social function, and social change.

Structure. The concept of social position is used to describe a social structure. A social position (often called a "social status") is defined by a set of rights and a set of duties. That is to say that the coordinates by which a position in social space may be located are rights, referring to what an incumbent of a position may expect of others, and duties, referring to what others may expect of him. These expectations are social norms or standards of conduct, based ultimately on moral values. The study of values per se belongs to philosophy and theology. But the study of valuations, the ways in which values are formed and held in the course of human behavior, is not merely allowed in scientific sociology but essential. It must be stressed that there is virtually unanimous agreement among sociologists today that a social order is distinctively a normative order.

If the structural parts of a social system are positions, where, then, does the individual come in? He comes in by taking various social positions. He may do so by ascription (if it is given to him, for example, his religious affiliation at birth) or by achievement (if he earns it, for example, a foremanship in a plant). There is, of course, no one-to-one correspondence between individuals and positions. One individual usually fills many types of positions, and each type of position is usually filled by many individuals. A specific position in an organization may be held by several people in succession, or by no one, when it is vacant.

What holds a position "in position" in a social structure is largely a matter of mutual support among positions, mutual recognition, and enforcement of rights and duties. Feelings of humiliation, for example, may be appreciated in psychological terms; but to humiliate means literally "to reduce to a lower position." There is some evidence that the upsets of everyday life, considered by many as an important concern for preventive psychiatry, are very often positional upsets, due to violations of vested expectations.

Function. A social role, as Linton puts it, "represents the dynamic aspect of a status." When a role is performed, the rights and duties of a social position are put into effect, and a social system functions.

Role strains for the individual may be patterned in various ways. One example is a high performance role, such as concert violinist or marathon runner, in which it is expected that the performer will go to marvelous extremes of taxing himself. Other types of strains are due to conflicts, in which two or more roles carried by one individual make too heavy a load or impose conflicting demands (such as home and career).

Illness itself, in its sociological aspect, has been conceptualized under the heading of "the social role of the sick person" or just "the sick role." It is a societal device for exempting an individual from his regular role demands, and it usually carries additional rights (secondary gains) to receive care and solicitude. But the sick role imposes the duties of wanting to get well, of seeking necessary help, and of cooperating in treatment. The physician plays a special part as the one who can formally pronounce that any particular taking of the sick role is legitimate or not legitimate (malingering). Failure to meet role demands would carry the stigma of deviant behavior, if the failure were not covered by the sick role; and the sick role must include the above-mentioned signs of good motivation, if it is to secure exemption for nonperformance.

Professional helpers also appreciate good motivation in their cases as a factor in eventual success, and they may often reject some types of cases, such as alcoholics or drug addicts, for apparent lack of motivation to get well.

The public stigma that attaches to mental illness in this culture is notorious, and it is a great detriment to afflicted individuals. People generally allow the sick role to mental patients but do not stop defining them as deviants. Indeed, many symptoms of mental disorders are acts that deviate from social norms; and many mental patients are not so earnest and cooperative as the sick role requires.

Compliance with social norms, however, is rarely demanded in absolute terms. There are various ways for allowing toleration of deviation, and there has been evidence of growing tolerance for and even acceptance of the mentally ill by the public at large.

Change. Socialization and social mobility are concepts that apply to ways in which individuals change and thereby contribute either to social stability or to social change.

Socialization is the process by which the individual learns to perform social roles. It applies not only to children but to recruits at any age. Anticipatory socialization refers to learning that goes on before a role is actually taken.

Social mobility refers to a change in social positions, usually the occupational position of the head of the household, taking occupation as the prime indicator of social rank for a family or single adult. It may be measured as intergenerational mobility (difference between parent and offspring) or as career mobility (the individual's own movement as an adult). Geographic

mobility refers to moving one's residence from one place to another.

Reference individuals and reference groups are two sources of orientation for learning content and style in new roles.

Each age cohort within a given group is socialized in a singular historic situation by a parental generation that was formed in another type of situation (such as a time of depression or of war). How do these shifting patterns affect the processes of child development and of adult adjustment in consequence? They seem to be a source of confusion and consternation for those who experience these processes and for those who study them.

The effects of social change on mental well being have been investigated. Findings by Leighton and his associates in the Stirling County study were consistent with their hypothesis on the ill effects of social deterioration in an area. Ruth Benedict's concept of cultural discontinuities postulates that the culturally normal life course may be costly to the individual's well being if it contains sharp breaks, as does the transition in this culture from adolescence to adulthood. Syme and his associates found associations between rates of coronary heart disease and four patterns of change: increasing urbanization of a stationary population and all three types of individual mobility—geographic, intergenerational, and career mobility. They postulate cultural mobility as the common factor, referring to external changes in the way of life to which the individual must adapt. In addition to the hypothesis that mobility induces illness, there is the "drift" hypothesis that illness induces movement of certain kinds. Both processes seem to occur, but it is usually hard to measure their respective contributions to observed rates of illness.

The whole maintains its parts. Structure, function, and change have been discussed as aspects of a system in which the whole depends on its parts—where they are, what they do, how they develop. A system thus dependent on its parts must somehow manage to maintain them in working order if it is to endure. Parts can go out of order in a number of ways, each way corresponding to a positive process (in parentheses, below) that keeps it from happening: The parts must not lose their distinctness, for instance, by fusing together (differentiation); they must not perish for lack of sustenance (allocation); they must not detach themselves from the whole (integration); and they must not underdo or overdo whatever they do, at least not beyond tolerable limits (regulation).

Differentiation. Social differentiation refers to the variety of positions that make up a social system. Leveling is a type of dedifferentiation in which individual rights tend to sameness, and role blurring refers to situations in which duties tend to sameness.

Dedifferentiation may occur suddenly in a situation where there is panic, such as in a fire in a crowded theatre. Role distinctions between house staff and au-

dience are lost, as are the distinctions among men, women, and children. Exits become blocked with masses of undifferentiated humanity.

Logically, dedifferentiation reduces variety among parts (social roles) and thereby sets limits on capacity to function. In practice, of course, society defends some differences more strongly than others. For example, we strongly control social differentiation by sex; transvestitism is made a crime and is considered a sign of illness.

Allocation. Social allocation refers to the socially patterned ways in which the needs and wants of an individual are met. Economics studies these processes insofar as they involve production, exchange, and consumption of goods and services by market mechanisms. Sociology projects these matters onto a wider screen. The kinds of rewards that can be had from a social system are placed under these main dimensional headings: class, status, and power.

Class is based on life chances in the market place. Status, here a synonym for prestige, is based on one's embodiment of the fulfillment of social values, as through a respected family name or by occupational attainment. Power is based on being in a position of control over events. These three dimensions are conceptually independent. Empirically, they can be discrepant, but they tend to be highly associated.

Differential allocation in these three dimensions produces social differentiation of an invidious kind, called social stratification. A stratum includes persons of roughly the same social rank. Social surveys often use a composite measure of over-all social rank called socioeconomic status, or SES, based on such indicators as education, occupation, income, rent, and area of residence. SES tends to be one of the strongest variables in social surveys on whatever topic; that is, it tends to show wide and strong empirical relationships.

For some empirical comparisons, it is valuable to consider the various indicators of SES separately. And for some conceptual comparisons, it is valuable to consider class, prestige, and power separately. Moreover, the concepts of class, status, and power can be used to distinguish not only types of rankings but also types of interactions. The ways of dealing for money or prestige or power tend to be distinctive. Also such dealings may blend in distinctive ways, as in the contrast between class politics and status politics.

Relations between social rank and mental disorder have been studied by various investigators in various ways. There is remarkable agreement on the finding that, the lower the social rank, the greater the risk in most nosological categories of mental disorder and in most symptomatic indicators. All three dimensions of social rank appear to contribute to the general finding, insofar as they can be separated by empirical indicators. Moreover, there seems to be an interaction effect from discrepancies in rankings among an individual's social positions, such as occupation of high

rank but an ethnic background of low rank or vice versa. Jackson found such departures from status consistency to be associated with psychosomatic symptoms.

Hollingshead and Redlich among others reported direct associations between quality of care received for mental disorders and social class rank of patients. There are many issues of measurement and interpretation on which such findings may be questioned, but if differences in quality (subtle or gross) are recognized in a thing, those differences will tend to affect the allocation of the thing. How that happens depends on how the dealings in that thing are organized. The allocation of care for the mentally ill may be organized along lines of one or another of the dimensions discussed—class, prestige, and power.

If care is organized predominantly on a fee-for-service basis, it is basically a market matter; and we may expect class differences in care. In the model used by the military services, access to care is a right of membership that applies to private soldiers and general officers alike; but generals do better than privates in that regard, not by issuing commands but because, by the value structure of the military, they have more prestige than privates. Finally, there are those who, viewing the care of mental health problems in a community context, see it as a matter of mobilizing the power of affected groups to win improvements in their conditions of life.

Integration and regulation. Integration refers to the act or process of making whole or entire. Social integration of an individual in a group refers to the extent to which he is joined (united, bound) to the group. It is a highly generalized conception that may be analyzed in many ways. Regulation refers to processes of keeping events within the limits set by some rule or standard. *Social regulation* of the individual by the group refers to the ways in which he is kept within the limits set by group norms.

The concepts of integration and regulation are discussed together to emphasize their conceptual distinctness while pointing to their closely intertwined empirical relations. A classic juxtaposition of these two concepts occurs in Emil Durkheim's study of suicide, in which he marshalled evidence to adduce four types of suicide in sociological terms: egoistic, due to underintegration; altruistic, due to overintegration; anomie, due to underregulation; and fatalistic, due to overregulation.

Acts of regulation by a group tend to foster the integration of the group; that is, the norms are strengthened by exercise. Thus, some deviant behavior is normal and perhaps necessary for group solidarity. Scapegoating and segregation of outgroups by ingroups are ways of activating these mechanisms.

Acts of regulation may be aimed to correct the malintegration of an individual. They may succeed, or they may boomerang by producing feelings of social alienation. Some degree of malintegration, as in a mar-

ginal member, may be of value to a group. Such members, because they are usually not so parochial or square as highly integrated members, can be valuable sources of innovation and criticism.

The concept of alienation and its correlates has been receiving much popular and scholarly attention. Seeman, in a much quoted article, has suggested five types of alienation: powerlessness, meaninglessness, normlessness, isolation, and self-estrangement. Dean has compiled the following suggested correlates from the literature: apathy, authoritarianism, conformity, cynicism, hoboism, political apathy, political hyperactivity or personalization in politics, prejudice, privatization, psychosis, regression, and suicide. In general, the concept of alienation appears in the thick of the efforts to study the processes by which the individual seeks a *modus vivendi* with society—his provocations, compensations, and decompensations—affected especially by processes of social integration and social regulation.

Empirical attitude measures have been devised for many aspects of alienation, notably the F (authoritarianism) scale from the seminal study of Adorno and his associates and Srole's A (anomia) scale.

Social Interactions

A social organization operates through the actions of its members with one another and outsiders. Saying that a firm or a group or a society does this or that summarizes the resultants of patterns of events at another level of analysis, that of social interaction. Interactions are more accessible than are organizations to everyday observation and common sense interpretation.

At the level of social interaction it is still the case that individuals take parts, but these are not necessarily parts in organizations, formal or informal. Interactional roles may be demarcated in terms of the structure of the situation in which they are played: the role of a stranger, a nonmember, a third party, a spoiler, a conciliator, an innocent, a clown.

Interactions between individuals are guided by each of the participants' definition of the situation. In the words of W. I. Thomas, "Things that people define as real, are real in their consequences." Inasmuch as definitions may be highly subjective, people may not know what to expect of each other in the absence of a common culture to establish the rules of the game. Moreover, because social processes sometimes operate perversely, prediction may be hazardous, even under a common cultural umbrella. Some things that otherwise would not have happened may happen because they were predicted (self-fulfilling prophecy); and some things may fail to happen because they were predicted (boomerang effect).

An interaction system is marked by complementarity of expectations, that is, some way in which the parts complete a whole; but the valence of com-

plementarity in any situation is not necessarily positive (cooperation). It may be negative (contention) or null (suspension).

Guidance of each part. A guidance mechanism may be analyzed for three kinds of functions: it must get relevant information (cognitive), match that information to an appropriate mode of response (affective), and check the response against governing standards (evaluative).

Cognitive. Social clues are guides to social positions. A married woman wears a wedding band on the third finger of her left hand (or of her right hand in the European fashion). A manual occupation is symbolized by a blue collar. An aristocrat is expected to distinguish himself by dress, bearing, and soft hands.

Social cues are guides to expected conduct. Our culture provides a clear signal for the ending of a formal interview: the person behind the desk stands up. If it is an informal visit, then the host must wait for the guest to decide to leave. There are tales of excruciatingly long visits by newly arrived Indian students, in whose culture it is the host who must say when a visit has ended.

Behavior problems of school children are often attributed to cognitive difficulties, such as a deficiency in sight or hearing, or cultural deprivation.

Affective and evaluative. An individual enters interaction situations with certain guidelines: beliefs, which are positions on questions of fact; affects, which are feelings pro or con toward things; and values, which are commitments to standards, especially moral standards.

Interaction may be considered the interplay of the set of wants (affects) and musts (values) of its several participants. But the structure of the game of interaction consists of more than the sum of such parts. This is illustrated by the story of the permissively managed nursery school children who asked, "Must we do what we want?"

The individual composes his guidelines and poises himself for interaction by his postures or attitudes toward things and issues.

Insight into the functions of attitudes and values in social interaction is gained by referring to two of the ways in which role performance may break down: embarrassment and scandalization.

Gross and Stone write: "Embarrassment occurs whenever some central assumption in a transaction has been unexpectedly and unqualifiedly discredited for at least one participant. The result is that he is incapacitated for continued role performance." They describe "role as consensual attitudes mobilized by an announced and ratified identity." In short, part of one's presentation of self for interaction is the projection of attitudes (perhaps not the same ones from situation to situation); if they are discredited, the interaction may suffer mortally.

Scandal occurs when someone is caught failing to

uphold the values for which his position stands. It is a violation of prestige that hurts the reputation of the individual who fills the position and also of the organization that contains it. If no one of high prestige can be assigned responsibility, then even very grave malefactions are not scandalous. Scandal is an alarm reaction at a failure of responsibility for social regulation. Because rank has its privileges, some may deliberately scandalize others as a way of asserting rank. But a scandal often severs role relations and, therefore, can make a position untenable.

The relations of expressed attitudes to actions, interactions, and organizational positions may be studied by social survey techniques. The concept of value homophily refers to the observed tendency of friends to see things in the same way (or stop being friends). Consensual validation refers to mutual confirmation of shared attitudes (sentiments) in a group. Cross-pressures arise when an individual finds that a conforming opinion for one of his major social positions contradicts that of another.

Expressed attitudes that are extremely rigid or extremely fluid may, of course, be indicators of personality dysfunction or breakdown. It is a vast area for the study of the interplay of psychodynamics and social dynamics.

Complementarity between parts. Personal relations between individuals may be, grossly speaking, positive, negative, or indifferent. That is to say that, in terms of their feelings, they may like or dislike each other or fail to do either one. The same gross possibilities apply to the nature of their interactions, independently of their feelings, depending on the complementarity of their role performances. Individuals may cooperate with or contend with or suspend their attentions to each other. These possibilities at the level of interaction are logically independent not only of the individual level of feelings but also of the organizational level of social eufunction or dysfunction. Competition, for example, may be required between some members of an organization in order to foster heightened performance among them. Empirically, however, there is usually a positive association between good personal feelings, cooperative role relations, and organizational eufunction.

Cooperation. Cooperative relations may serve mutual personal ends directly, as when one hand washes the other. Or, if their direct purpose is organizational, they may serve personal ends indirectly through the fostering of group morale. At its highest levels, morale seems to create conditions in which the individual accepts organizational interests as his own, and the various ways in which the whole maintains the parts—differentiation, allocation, integration, and regulation—seem to be taken for granted or ignored.

Juveniles and senior citizens are two social categories that have gained special psychiatric notice. In this social system, neither group normally has important roles to perform. Thus they are blocked from

chances for prestige (organizational) or esteem (interactional), with presumptive damage to self-esteem.

Contention. Many of the institutional spheres normally operate by an adversary system: competition in the economic sphere, opposing counsel in law courts, and opposing candidates for elective office. It is taxing to be a contender and dispiriting to be a loser. For the individual, contention may help to develop strength and stamina, but it may be costly through strain of effort, conflict of motives, and punishment from the opposition. It is very difficult, even in imagination, to engineer an optimal role for contention in a social system.

Suspension. In social life, one is expected to be his brother's keeper in many ways, but not limitlessly. There are some areas that, under most conditions, are subject to suspension of interaction. The individual is accorded rights of privacy and also duties of decency. An analysis of these complementary concepts turns on the concept of social visibility, which is a far more portentous matter than it may seem offhand. Visibility refers to exposure to public notice. For certain ends, like finding customers in a market or being appreciated for one's affluence (Veblen's conspicuous consumption), visibility is a necessary condition. But where freedom from attention is desired, invisibility is to be prized.

Privacy rights are analogous to property rights in that they extend to delimited areas, they allow of exceptions, and one may refer to their violation as invasion. *A right of privacy consists in the enjoyment of social invisibility.* It may be extended to things, like dandruff or a physical handicap, that are perfectly visible in a physical sense.

There are social norms governing the underexercise of privacy rights. In other words, the individual has obligations to keep certain things of his socially invisible. These norms come under the heading of decency. Things like billboards and sound systems in public places have been fought as invasions of privacy, on the grounds that privacy consists in the right to be left alone. But the latter is only one means of being accorded privacy, and not an essential means. A public nuisance violates decency by failing to keep things invisible that should be so. It invades one's attention, but not one's privacy, which is one's own right to invisibility.

Norms of privacy and decency are of extreme importance to psychiatry because the psychiatrist works with patients under conditions of extreme liberalization of these norms as they apply in other spheres, even that of the family. These liberties are legitimate yet somehow suspect. Part of the public stereotype of the psychiatrist is that he can penetrate privacy, seeing what was intended to be invisible and creating feelings of indecency. When a psychiatrist goes outside of the clinical setting to practice community mental health, he may have to overcome such

feelings in the people, such as community leaders, with whom he must deal on matters of policy.

Research in Sociology and Psychiatry

The following summaries of three research projects are meant to convey what sociological research in psychiatric problems has been like. These were chosen (omitting from consideration studies that are described elsewhere in this volume and seeking variety of subject matter) from among the best known work in the field.

Social class and mental illness. Hollingshead, Chairman of the Department of Sociology and Redlich, Chairman of the Department of Psychiatry at Yale, studied the urbanized community of New Haven, Connecticut, consisting of that city and five surrounding towns, during parts of 1950 and 1951.

Design. The research project was multiplex, consisting of five main parts: (1) a census of psychiatric patients, (2) a sample survey of the population at large, (3) a study of psychiatrists, (4) a study of the community, and (5) a controlled case study.

The psychiatric census, the heart of the project, aimed to identify all persons who, as residents of the study area, entered a course of psychiatric treatment anywhere and were in that course for any of the interval from June through November, 1950. To be included, a treatment facility had to be a private psychiatric practice, a psychiatric clinic, or a mental hospital; but it did not have to be in the study area. Thus, the private hospital search included all licensed institutions in seven contiguous states and some others farther afield.

Who escaped this net? Persons who may have been ill but received no treatment or else received some treatment that was under the auspices of a specialty other than psychiatry, such as social work, clinical psychology, or pastoral care, were omitted by design. Some others may have been omitted through clerical error or because they went to a remote facility. Finally, a large group was known to be missing because their agent of treatment refused cooperation. All the 22 hospitals and seven clinics that were approached did cooperate. Out of 66 private practitioners known to have eligible patients, 20 practitioners, who earlier had reported a total of 31 eligible patients, refused to share data. Of those 31 patients, 30 went to New York City for treatment. The researchers estimated that 40 to 50 patients from the intended target group were left out of the census; that amounts to about 2½ per cent of the total target group, the census having found 1,891 patients.

The instrument for data collection was a patient schedule. It was divided into a sociological part, focused on the patient's social and family history, and a psychiatric part that covered the therapeutic history, including the types of treatment the patient received and a diagnostic impression by his psychiatrist. A sociologist and a psychiatrist abstracted their re-

spective parts from the clinical records of the institutional patient. Each private practitioner gave the information on his patients in an interview with a project psychiatrist.

The sample survey described the composition of the entire population from which the patients came. It allowed comparisons between the patients and the rest of the population, and it provided denominator figures for calculating patient rates.

The study of psychiatrists allowed comparisons between aspects of psychiatric practice and characteristics of the practitioner. It also was relevant to the description of psychiatric facilities for the study area and to characterization of types of treatment that patients received.

The community study gathered historic and contemporary information on matters pertaining to psychiatric care for the community and on the social class structure of the community. The measure of social class status for the study was Hollingshead's index of social position, which is based on the individual's education, occupation, and area of residence. Each indicator is valued numerically, and the three are combined into a score by standard operations. A detailed knowledge of the particular community is needed to map and evaluate residence areas as indicators of social status. All the persons under study—patients, sample survey respondents, and psychiatrists—were placed in a scheme of five classes from class I, the highest, to class V, the lowest. (Because class I was relatively small, the two highest classes were often combined as class I–II in the presentation of findings.)

The controlled case study included 50 patients, selected by criteria of age (22 to 44), color (white), class (III and V only), and diagnostic category (25 psychoneurotics and 25 schizophrenics). These same criteria, when applied to the patient census, showed that the selected cases were not significantly different, with respect to such other variables as age and sex, from the pools from which they were drawn. The case study, the researchers said, "was designed to explore systematically interrelationships between sociocultural and psychological factors in the development of psychoneurosis and nuclear schizophrenia in two nonadjacent social classes."

What did the researchers want to accomplish by this battery of interrelated operations? In general, they wanted to bridge a gap between sociology and psychiatry. They chose social class status on the sociological side and treated mental illness on the psychiatric side as their focal variables. Their central interests were in the relation of social class to occurrence of mental illness treatment methods.

They formulated five major hypotheses, to be tested by their data: position in the class structure is related to (1) prevalence of treated mental illness, (2) types of diagnosed psychiatric disorders, (3) types of psychiatric treatment administered by psychiatrists, and

(4) social and psychodynamic factors in the development of psychiatric disorders. The final hypothesis was that (5) mobility in the class structure is a factor that is related to development of psychiatric difficulties.

Class status and cultural characteristics. The authors sketched the distinctive styles of life that they found in each class.

Class I, containing the community's business and professional leaders, has two segments: a long established core group of interrelated families and a smaller upward mobile group of new people. Members of the core group usually inherit money along with group values that stress tradition, stability, and social responsibility. Those in the newer group are highly educated, self-made, able, and aggressive. Their family relations often are not cohesive or stable. Socially, they are rejected by the core group, to whom they are, however, a threat by the vigor of their leadership in community affairs.

Class II is marked by at least some education beyond high school and occupations as managers or in the lesser ranking professions. Four out of five are upward mobile. They are joiners at all ages and tend to have stable families; but they have usually gone apart from parental families and often from their home communities. Tensions arise generally from striving for educational, economic, and social success.

Class III males for the most part are in salaried administrative and clerical jobs (51 per cent) or own small businesses (24 per cent); many of the women also have jobs. Typically, they are high school graduates. They usually have economic security but little opportunity for advancement. Families tend to be somewhat less stable than in class II. Family members of all ages tend to join organizations and to be active in them. There is less satisfaction with present living conditions and less optimism than in class II.

In class IV, 53 per cent say they belong to the working class. Seven out of 10 show no generational mobility. Most are content and make no sacrifices to get ahead. Most of the men are semiskilled (52 per cent) or skilled (35 per cent) manual employees. Practically all the women who are able to hold jobs do so. Education usually stops shortly after graduation from grammar school for both parents and children. Families are much different from those in class III: families are larger, and they are more likely to include three generations. Households are more likely to include boarders and roomers. Homes are more likely to be broken.

Class V adults usually have not completed elementary school. Most are semiskilled factory workers or unskilled laborers. They are concentrated in tenement and cold water flat areas of New Haven or in suburban slums. There are generally brittle family ties. Very few participate in organized community institutions. Leisure activities, in the household or on the street, are informal and spontaneous. Adolescent boys

frequently have contact with the law in their search for adventure. There is a struggle for existence. There is much resentment, expressed freely in primary groups, about how they are treated by those in authority. There is much acting out of hostility.

Paths to the psychiatrist. A person entering psychiatric treatment for the first time may be seen as passing through four stages: abnormal behavior occurs; it is appraised as a psychiatric matter; there is a decision that help is indicated; and the decision is implemented. The authors discussed class differences in all four stages. Their figures, on source of referral, apply only to the fourth stage, where they found clear and strong associations with social class. For example, among those classified as neurotics entering treatment for the first time, the referrals by private physicians were much greater in class I-II (52.5 per cent) than in class V (13.9 per cent). The police and the courts referred no one from class I-II, but they referred 13.9 per cent of class V patients. Social agencies referred 1.4 per cent of class I-II and 36.1 per cent of class V.

Class and prevalence of disorders. In confirmation of their first hypothesis, the researchers found "a distinct inverse relationship does exist between social class and mental illness." In terms of treated psychiatric illness per 100,000 of the population, the rates are 798 over-all, 556 for class I-II, 538 for class III, 642 for class IV, and 1,659 for class V. Thus, the really sharp dividing line is between class V and the classes above it.

The relationship between the two major variables—class and treated prevalence—was explored by the use of five social background variables as controls. These were age, sex, race, religion, and marital status. It was shown that these other social variables, either singly or in pairs, did not explain away the relationship of major interest in the study design. The analysis did not dwell on any social variables other than class (that is, the index of social position) as interesting in their own right in relation to the patient rates.

Class position and types of mental illness. The second hypothesis, relating social class to types of disorders, was also supported. A simplified diagnostic scheme drew a major distinction between neuroses, divided into seven subgroups, and psychoses, divided into five subgroups. The over-all prevalence rates for the neuroses were highest in class I-II and tended to fall as class level fell; but for the psychoses the rates rose sharply as class level fell; and they rose very sharply from class IV to class V (from 518 to 1,504 per 100,000). The analysis by class of the diagnostic subgroups, especially among the neuroses, shows considerable variety of patterns. The same applies to the division of the total prevalence rates into components of incidence, reentry, and continuous rates.

Treatment process. The researchers confirmed their third hypothesis by showing that social class was

related to where and for how long patients were treated and what kind of therapy they received.

The analysis of this material was relatively complex. It involved three previously discussed variables—social class, diagnostic group, and components of prevalence—and four new ones—type of facility, type of therapy, length of therapeutic sessions, and duration of treatment.

The facilities covered in the study were 42 private practitioners, 10 private hospitals, 7 public clinics, 6 state hospitals, and 5 veterans' hospitals. Two out of three patients were in the state hospitals and nearly one in five with private practitioners. Consider the relation of social class to type of facility among neurotic patients treated for the first time: with private practitioners were 85.7 per cent of class I-II and 9.8 per cent of class V; in state hospitals were 19.7 per cent of class V and none of class I-II.

The major treatment types distinguished were various types of psychotherapy, organic therapy, and custodial care. Looking again at neurotic patients; those in classical analysis or analytic psychotherapy were 46.9 per cent of class I-II versus 4.9 per cent of class V.

Length of sessions among neurotic patients treated by private practitioners varied greatly by class. In class I-II, 94.3 per cent had the longest session (50 to 60 minutes) versus 45.4 per cent of class V; and 36.4 per cent of the latter had the shortest session length (15 to 30 minutes), which was more than 10 times the percentage of any other class.

Median number of years in treatment varied by class directly and moderately among neurotics. It varied by class inversely and sharply among psychotics.

Expenditures on treatment. The researchers found that "expenditures on treatment are linked in highly significant ways with class status in each type of psychiatric facility." In private mental hospitals, the higher classes, with longer terms of hospitalization, spent more in toto but spent less per day, as a result of having better access to discounts. In clinics, on the other hand, fees tended to be equal, but total value of treatment rendered varied directly with class. "The clinics spend eight times as much treating each class II patient as they do each class V patient."

Psychiatrists. Psychiatrists were divided into two main classes: (1) those with an analytic and psychological orientation, called the A-P group, and (2) those with a directive and organic orientation, called the D-O group. The division was based on type of training for therapy and on types of therapy employed by the practitioner. Admittedly, it was a somewhat arbitrary distinction, allowing of considerable variations. And yet, empirically, it turned out to be a most powerful discriminator of broad clusters of traits of various kinds, amounting virtually to a division of psychiatry into two separate fields of practice.

In the study area, the university psychiatrists were

largely A-P and the public hospital psychiatrists largely D-O.

The D-O psychiatrist, in contrast to the A-P, wore a white coat, rather than a business suit, in a clinical setting. He did not use a couch. He made house calls, worked uneven hours, accepted emergencies as a daily occurrence, usually saw his patients for short periods (15 to 30 rather than 50 to 60 minutes), and saw them weekly or monthly rather than daily. He charged less per visit but averaged about \$25,000 a year to the A-P's \$22,000.

All the psychiatrists in the community were in class I, except for 5 per cent in class II. The A-P group tended to be much aware that social stratification existed, but the D-O group tended to deny it and to be embarrassed by questions about it. Only 8 per cent of A-P group were of old American stock, compared with 44 per cent of the D-O group; 58 per cent of the A-P group were first or second generation, compared with 38 per cent of the D-O group. A related finding was that 83 per cent of the A-P group were from Jewish homes, compared with 19 per cent of the D-O group; and 12 per cent were of Protestant background, compared with 75 per cent of the D-O group. The A-P group showed far more social mobility than the D-O group.

Conclusions. The researchers, focusing on relations between social class and mental illness, pointed out that Americans prefer to avoid the two facts of life they had chosen to study. Actually, they did not themselves encounter mental illness head on. They studied, by indirect observation, patients under the care of psychiatrists. Carefully stressing that limitation, they offered only tentative inferences.

The empirical findings of the study amply bore out the hypotheses on relations between class position and how many cases were treated, of what diagnostic types, and by what types of psychiatric treatment.

In a discussion of the neuroses, this terse generalization was offered: "The class V neurotic behaves badly, the class IV neurotic aches physically, the class III patient defends fearfully, and the class I-II patient is dissatisfied with himself."

On the phenomena of mental illness and social class, the authors offered these inferences: (1) "Each type of mental and emotional disorder occurs in all classes, but in different proportions." (2) The fact that psychiatric facilities differ in the status level to which they cater seems to be related to the differential distribution of disorders by class. Extremely regressed schizophrenics, for example, are rarely seen in good private hospitals. (3) The content of mental illness reflects social and cultural conditions. (4) Perceptions of mental health are class-related. (5) Observed relations between sociocultural variables and the prevalence of treated disorders do not establish that the former are the essential and necessary conditions in the etiology of mental disorders.

In suggesting some applications for their study, the

authors stressed the need for more knowledge of social factors in psychiatry, new treatment methods, new approaches to professional training, better public mental hospitals, evaluation of psychiatric care ("Class V needs help most—social and psychiatric—and gets it least"), and improved public health education in mental health.

Psychiatric hospital as a small society. William Caudill studied a small psychiatric hospital attached to the medical school of a large university. He gathered his data as a participant investigator during 1951 and 1952. Before that, in 1950, he had been a concealed observer in the same hospital, posing as a patient. That venture caused some shock to the hospital's members when the impersonation was made known.

Caudill, an anthropologist, sought to develop a distinctively sociological thesis in his book. He was "concerned with a search for an understanding of the broad context of the therapeutic process in a psychiatric hospital." He believed and sought to show by the evidence of multiple interrelationships that that broad context constitutes a social system. The functioning of that system, moreover, "affects the behavior of the people who make it up in many ways of which they are unaware."

Design. The research consisted of three interrelated studies: (1) A ward observational study, based on detailed daily observations in two 8-week periods, covering first the men's locked ward and then the open wards for both sexes. Each of these periods consisted of more than 300 hours of observation. (2) A small group study, covering the daily administrative conference, that began before and continued through the 16-week period of the ward studies. The data for this conference study consisted of an essentially verbatim record of more than 120 consecutive conferences. (3) An attitude survey, which began in the 4th month of the project and lasted for 7 months. The respondents were both patients and staff. The questions were based on a series of specially drawn sketches that depicted everyday situations of life in the hospital.

One type of data was missing from the project, much to the regret of the researcher. He was not able to get regular and reliable reports on what happened during the psychotherapeutic hours. He was especially interested in relative progress or regress in therapy as a variable that might show relations to events in the broad social context. Such data would have allowed a direct test of a ground swell theory, which posits that a majority of the patients on a ward do well or poorly at a particular time.

Small group findings. The daily administrative conferences were held each morning except Sunday, usually lasted some 20 minutes, and usually included 13 persons, divided among senior staff, residents, the supervisor of nurses, charge nurses, and other specialized personnel.

One of the findings of this study, though very sim-

ple, was remarkably consistent and strongly supportive of the main thesis of the book. It was found that the amount of talking each person did was a function of rank in the hospital. Everyone in a higher status group talked more than anyone in a lower status group, the most passive resident more than the most extroverted nurse. Within each role group, the amount of talk was in order of rank. Among the five residents, nominally of equal rank, there was a consistent order within each of three series of 21 conferences. When the senior staff members were asked to rate the five residents in order of clinical competence, it was found that the ratings corresponded almost perfectly with the rank order on amount of talk during the conferences.

Attitude findings. The attitude study, based on sketches of hospital life, showed many discrepancies in patterns of perceptions among role groups. Surprisingly, the senior staff and the patients showed very similar patterns. It was surprising in that it was found that the senior staff were often unfamiliar with physical aspects of the ward because they were so seldom there. Residents and nurses had different distinctive patterns. Nurses, for example, tended to be optimistic about patient contacts that were administrative but pessimistic about those that were therapeutic. Patients showed exactly the reverse pattern.

Ward findings. The findings from the ward observation study involved much narrative material. The findings pointed to such things as unintended consequences of administrative decisions, failure of communication, and conflicts between administrative and therapeutic objectives. One highlight was an account of a collective disturbance which centered about a television petition by the patients. It was marked by tension among patients and staff, mainly as a result of poor communication. The author was able to analyze the incident into a sequence of four phases, and he speculated that it may be possible to develop monitoring techniques to predict the tenor of events on the wards. The disturbance illustrated the author's conception of "a covert emotional structure underlying the overt formal and informal structure of the hospital."

Conclusions. The author pointed to some distinctive social-structural features of the psychiatric hospital as being especially relevant to its effectiveness. There is dual control, a division between administrative and therapeutic functions that has a high potential for causing conflicts. The author questioned the assumption that these two kinds of functions are incompatible and suggested that they may beneficially be combined in one person. Another similar source of conflict is multiple subordination, where several independent chiefs have authority over the same worker. Another feature, one that pertains to hospitals in general, is the use of mobility-blocked roles. The levels of personnel are marked off by lines, which personnel do not cross within the system. Attendants do not rise to become nurses, and nurses do not rise to become

physicians. This feature induces formalized relations and greatly affects the content and flow of communications.

The author called for greater openness among persons who operate existing psychiatric hospitals and greater self-examination, comparable to that demanded of the psychiatric patients, if the goal of a therapeutic community is to be reached. And he called for a willingness to consider new departures and new models for the physical and organizational structure of psychiatric hospitals.

Closed ranks. John Cumming is a psychiatrist, and Elaine Cumming, his wife, is a sociologist. In 1951, they conducted an intensive 6-month educational campaign in Blackfoot, a Canadian town with a population of 1,500, attempting to modify public attitudes toward mental illness. They used a variety of media, such as lectures, the press, radio, and films. Their presentations involved concepts and materials that were then generally available. They were very careful and hard working in their efforts to achieve good community relations.

Design. They employed an experimental design to evaluate the effectiveness of their campaign. That involved a second town, 150 miles from the first and similar to it, as a control community. In both towns, there was one wave of interviews before the educational campaign in Blackfoot and a second wave after it. The control community received no stimuli from the researchers other than the interviews. Two attitude scales, a social distance scale and a social responsibility scale, were the intended means of measuring before and after conditions in the two communities.

Results. Before the educational campaign, the scores in both communities tended to be low in both scales, indicating much prejudice against the mentally ill and little acceptance of responsibility toward them. After the campaign, the researchers found no trend of change. The two communities remained at about the same level as each other and unchanged from the first wave.

The researchers met an effect in the experimental community that compounded their chagrin. As the educational campaign went on, the community reacted with growing hostility and aggression that was, for the most part, aimed not at the educators but at the second wave interviewers. Some 6 years after the experiment, the authors published their report on what happened, giving their reflections on what it all may have meant.

Findings. The project was designed to allow not only an experimental test of the educational campaign but also an exploratory analysis of data on public attitudes toward mental illness. Some interesting findings emerged.

The researchers put together a series of attitude questions that they thought belonged to a single dimension of constructive versus nonconstructive attitudes. But they found that the items fell into two

dimensions: social distance (for example, "I would be willing to room with a former mental patient") and social responsibility (for example, "I would feel partially responsible if a member of my family had a serious mental breakdown"). Each dimension was measured by a scale that reflected responses to several questions. It was found, surprisingly, that these two scales were statistically independent of each other and bore different patterns of relations to other variables. Social distance (nonacceptance) scores varied directly with age and inversely with education. Social responsibility scores were unrelated to either age or education, but they did relate to the respondents' ideas about the causes of mental illness. Those who saw social or economic causes scored highest on social responsibility. Next came those who saw personality causes. Lowest were those who saw either moral or biological causes for mental illness.

Conclusions. Why were the research findings on the educational campaign negative? Was it, perhaps, simply a result of faulty research methods? The authors acknowledged that their campaign was uneven in its coverage and that their sample in Blackfoot (540 respondents, equal to 60 per cent of the adults in the community) was biased. Lower class persons were underrepresented. Also, the design allowed only trend measures of net change in the group and not turnover measures on actual changes by persons. Finally, the design did not include any measures of how much each person may have been exposed to educational material from the campaign or other sources. It seems hardly likely, however, that these or any other methodological points can explain away the experimental evidence of resistance to attitude change.

The authors tried to explain what happened by means of a theoretical discussion. They discussed "the patterned reaction to mental illness in our society." From a societal viewpoint, mental illness is a form of deviance from social norms. Any deviant behavior upsets the equilibrium of the social setting in which it occurs, and the way in which the deviant person is treated may be expected to serve the function of helping to restore social equilibrium. It is this societal function that lies behind the postulated patterns of values, beliefs, and actions. The pattern is characterized by themes of denial, isolation, and insulation of mental illness in this society. Confronted by irrational behavior due to mental illness, the citizen's first tendency is to normalize the behavior. When this denial of illness is no longer tenable, the next step is physical and social isolation of the deviant. Finally, there is insulation of the entire problem by additionally denying that these elements of the pattern may have posed any civic problem.

The project induced hostility, the authors believe, because of the intensiveness of their campaign. Theirs was a highly concentrated assault of high social visibility. It was not so much a matter of arousing anxiety

in individuals as of posing a threat to the equilibrium of the community. The community responded by asserting the solidarity of the sane. It closed ranks against the intruders.

Suggested Cross References

Further comments on the role of social and cultural determinants in normal and pathological behavior may be found in the chapter dealing with the various cultural and interpersonal psychoanalytic theories (Chapter 7) in Area C, on current theories of personality and psychopathology. Discussions of sociocultural influences on specific psychiatric problems, such as schizophrenia, alcoholism, suicide, delinquency, and mental retardation, may be found in the sections dealing with these topics in the clinical areas of this book. For an example of the application of sociological concepts to clinical psychiatry, see Section 36.1 on milieu therapy by Stainbrook in Area G, on psychiatric treatment.

4.3 THE ROLE OF THE FAMILY IN PSYCHIATRY

STEPHEN FLECK, M.D.

The family is the universal, primary social unit and, therefore, must occupy a central position in any consideration of social psychiatry. As current psychiatry and medicine encompass the study and understanding of the cell and its elements, of cellular organization and integration into organs and organ systems, and of their orchestration into a biopsychological whole that is the organism, so is that organism's behavior in and interaction with its environment important for the understanding of health and disease. Knowledge of the social elements and parameters of this environment is as essential to diagnosis and treatment as is reliance on laboratory data on body chemistry and the nature of food, water, and air supply.

The first social environment for every human being is his biological family or its substitute. If the latter, it will ideally be adoptive parents, who take over at the earliest possible time after birth. Usually, however, one family provides offspring with both his biological and cultural heritages.

The family is, therefore, an important sociocultural institution, the keystone of society, and every human group has devised traditional prescriptions and proscriptions to ensure that the family fulfills its biological and enculturating tasks. In this way, the family is both the link between generations that ensures the stability of the culture and also a crucial element in cultural change. The biological functions of the family are usually left to the nuclear family, especially to the mother, but the enculturating functions may be assigned to members of the extended family or even to nonrelated persons in the community. In Western society, both of these tasks have rested with the primary family, although not always with the primary nuclear family, as is most usual today.

History of Family Studies

Sociocultural studies. Scientific study and knowledge of the family have a rather recent history, especially in the context of psychiatry, but preoccupation with the family as a sociocultural institution is as ancient as human history. Three of the Ten Commandments specifically concern family relations, and every religious doctrine contains many specific rules and taboos about family structure and family duties. Equally ancient are concerns about family dysfunctions. Athenians deplored the alleged decline of family tradition and cohesion as endangering the state and society; the decline of the Roman Empire

has been attributed, among other causes, to the family's failure to inculcate the earlier moral standards and discipline. Throughout history major social upheavals have been examined in the light of changes in family life. Today this age-old thesis finds expression in more scientific endeavors, such as the current interest in cross-cultural comparisons, which seek precise correlations between national characteristics and family practices.

The causal relationships between family characteristics and social change or human history are circular and complex rather than unidirectional. Because of the family's central importance in human development, not only historians and social anthropologists, but also legal scholars, economists, philosophers, and sociologists have studied and written about the family. However, some of our most perceptive insights derive from literature, for instance, *Oedipus Rex*, *Hamlet*, Strindberg's *The Father*, and O'Neill's *Long Day's Journey Into Night*.

Psychiatric studies. Although the medical profession has prided itself on its family physician, this designation is based on his identical role with all members of a family and not, until recently, on any formal knowledge of family dynamics and their institutional characteristics. Historically, such endeavors in Western medicine can be measured in decades. Freud, although aware that his discoveries pertained primarily to family processes, chose to study and treat family pathology only in individuals. He concentrated on the investigation and conceptualization of his patient's psychic apparatus, isolated from its usual environment in the stark setting of the analyst's office. He thereby limited the social parameters to the analyst-patient dyad, a situation in which a person can relive family experiences through the phenomenon of transference.

Not until 25 years after Freud's first accounts of family-related unconscious processes, such as his rediscoveries of *Oedipus* and *Electra*, of the family romance and incest, did the first psychoanalytic effort to conceptualize family processes appear in print. At about the same time, investigation and clinical consideration of family members began in the American child guidance clinics. But, in clinical medicine and psychiatry, family histories have continued to focus mostly on familial incidence of disease and on hereditary patterns, not on family dynamics. In psychiatry some investigation of sociocultural constellations in families of patients according to diagnosis began in the 1930's, but direct clinical and research study of the family as a group did not begin until the 1940's. Despite the existence of an extensive sociological literature on family life, despite scholarly studies of family law, and despite anthropologists' preoccupations with non-Western family systems during this century, medicine and psychiatry continued to focus on the individual patient and the

doctor-patient relationship. Only in the last 20 years has there been rapidly increasing clinical scientific interest in and appreciation of the family as the most significant social force in human development, specifically in personality development, and hence as a potent agent in personality disorders. The family, therefore, is not only the keystone of society but also a key to understanding the humanness of the human being, including his failures as a human.

Marriage

Marriage is, of course, an integral part of and constitutes the basis for the family in most societies. But it needs to be considered also as an institution somewhat apart from the family, and it must be evaluated in each instance along a range of sociocultural and idiosyncratic contingencies.

Purposes of marriage. A universal biopsychosocial need for completion and fulfillment of oneself through the intimate life with another exists among humans and some other species, and two people may undertake marriage solely for their mutual satisfaction, without intent or capacity to establish a family. In Western society today, this definition of mutual satisfaction could be exclusively that of the two partners, although their definitions would necessarily reflect the cultural and psychological norms or deficiencies they have absorbed into their personalities during their respective developments. Western society would not interfere with such decisions or plans to produce no offspring, the needs or demands of spouses' parents or collateral relatives to the contrary notwithstanding. Other cultures may dictate in these matters. In extended family systems, parents may achieve neither full independence in these respects nor full authority over their own offspring, and failure to produce offspring can lead to dissolution of the marriage by either partner or by outsiders. On the other hand, marriage may also be undertaken in our society solely for the purpose of procreation, and in some religions it is indeed so prescribed, even if not always practiced.

Subconscious purposes. From the clinical vantage point, most marriages fall somewhere between these extremes of intent and purpose, one extreme being nonfamilial and the other 100 per cent family-oriented. It is most important for the clinician to appreciate that the spouses' respective explicit intents and beliefs may be at variance with the implicit or subconscious intents and wishes that lead them to marriage. For instance, one spouse may agree to marriage determined not to have children, and the other spouse may accede to this condition, quite prepared not to honor the agreement after marriage, or the other way around. Such behavior need not be a conscious or a designed betrayal; both spouses may intend to honor such agreements but later find that they cannot resist their own subconscious opposite desires or needs. For instance, Catholics may have

increasing guilt feelings over birth control, or one or more of their parents who aspire to the status of grandparents may exert pressure on the couple.

Depending on the partners' culture, they unite in marriage because they want to, because it has been arranged for them by their parental families, or because of a combination of these prescriptions. In the West, partners choose each other by and large on the basis of their feelings and hopes, be they realistic or not. Among the less conscious motivations and unrealistic factors that lead to marriage are many neurotic tendencies and needs. Most common among these is probably the use of marriage to achieve independence from the family of procreation which the young person cannot accomplish as an individual. This brings to the marriage certain dependency needs, which are likely to result in expecting parental care from the spouse. Another such factor is social pressure, especially on girls, from one's family or peers, that marriage at a certain age is an essential earmark of success.

Not all unconscious or external determinants need be unsound. The choice of a marital partner is a complex process, and a certain intuitive sense of personality fit between two people seems to operate effectively at times, even if neither spouse can account for it explicitly. There are many paths to marriage, sound and unsound foundations for family life, but spouses can build sound relationships even if they have united for ill considered reasons. One of the chief criteria for a successful marriage is that it furthers individual growth and growth as a unit.

Changes in industrialized societies. The personalities and the sociocultural values two individuals bring to marriage determine the nature of their relationship more than do their hopes, dreams, and intentions during courtship. This is particularly so now in industrialized societies, where marriage and offspring have shifted during this century from being economic advantages and even necessities, to being economic liabilities. The basis for marriage and for marital continuity has changed from tangible issues to the intangible necessities and requisites of companionship, encompassing physical, intellectual, affectional, and social facets. Although the partners can share the economic burdens, they rarely can do so side by side, as they would in dividing complementary tasks on the farm. Maintaining a house and household can be reduced to a minimum of labors, leaving as the major shared goal family life itself, together with the care of the offspring.

Sharing family responsibilities, however, has been made much more difficult by the absence of the husband from home during working hours, and, if he is ambitious, working hours may approach the entire waking hours of the family on many days. Hence, when there is concern in present day America about the husband's declining role in the family, these sociocultural givens of an industrial society are probably

more responsible and pertinent than speculative clichés about the decline of masculinity or the ascendancy of masculine strivings on the part of women. It must be appreciated that a boy of our age, after his school day with women teachers, does not return to a home where a father works. Such a youngster may hardly ever see his father at work, the nature of which may be very difficult for a young child to comprehend. The burden of making an absentee husband a live and appropriate image for the children often falls on the wife and depends, therefore, on the marital relationship.

Marital coalition. The marital coalition may be defined as those interactional patterns that the spouses evolve to provide, at first, for their mutual satisfaction. Later, in the structure and dynamics of the family, this coalition must serve the age-appropriate needs of the children and still maintain an area of exclusive relationship and mutuality between the parents. One of these parental sectors is sexual activity, interdicted to children in our society. Mutuality denotes the spouses' interactive patterns on implicit and explicit levels, the sharing of feelings, and the conveying of respect and appreciation of the spouses to each other as well as to others.

Sex-linked roles. An important function of this coalition in family life is the mutual reinforcement of the spouses' complementary sex-linked roles. As parents, they represent culture-determined masculinity and femininity, not only as individuals but also through the other spouse's support and approval. Another facet of the coalition is the conjugal role divisions and reciprocities the spouses establish for themselves. These role allocations and the decision-making methods vary with each socioeconomic class. According to Bott and to Rainwater, upper class spouses believe that their role divisions are equal and complementary but that husbands make more decisions. Lower class spouses, except for the lowest group, also state that their role allocations are joint and complementary but that wives make more decisions than husbands.

Effects of isolation. Industrialization and social and geographic mobility have isolated the nuclear family, adding to the critical importance of the marital coalition in the life of the family. Newlyweds may well seek isolation initially, but in the process of adjusting to married life, friends and relatives can be useful. Nowadays marriage is often followed by a move to new surroundings, strange for both partners. Whereas living apart from one's family of origin is considered desirable, letters are not the forum in which one inquires about a recipe for tonight's supper or in which one reports and gains perspective about the first marital altercation. These items may seem trivial, but professional experience with marital problems indicates otherwise; minor problems and disharmonies can easily accumulate and fester. Physicians can help as marriage counselors, but young

people have few occasions to seek out health resources until pregnancy occurs. Prenatal care, therefore, offers an important opportunity for remedial marital counseling and for the prevention of future marital and family disorders.

Because the marital partners usually become the sole or at least the major sources of identification for their young, the spouses' personalities and the marital coalition are much more critical today for the personality development of the children than in the past. In extended family systems a child has many adults of his sex to use for identification. This is still true to some extent in subcultures where grandparents and the parents' collaterals live nearby, albeit in separate households. Living isolated from close relatives deprives the spouses of the advantage of sharing parental functions with an extended family group and leaves each child with little alternative but to view his parents and their relationship as exemplary. Spouses must depend on each other in crises without ready availability of a relative to assume the tangible household or income-producing duties of a disabled partner. In this sense, the demand for individual adjustment and maturity and for effective role complementarity are more stringent than in earlier times. Moreover, most offspring will have no other adult models at home in a continuing way to compensate for model deficits in one or the other parent. Problems in the isolated nuclear family, therefore, tend to become circular: marital difficulties affect children adversely, and a difficult or ill child strains the marital coalition.

Individual adjustments. In a free society, spouses depend still more critically on their inner resources because, compared with other cultures, there are relatively few social rules or rituals concerning marriage. In the West, society and religion concern themselves primarily with the beginning of marriage and with death and divorce. Aside from registration of the newborn, society intervenes with a family only if gross undercare or mistreatment of the young is made evident. Otherwise, marital partners are on their own to mesh their personalities into the kind of bond and coalition they desire and are capable of, but their capabilities may fall short of their desires. If this happens, they may seek help through counseling, which is available only to a very limited extent, or they may live on in conflict and disharmony, or they may seek divorce.

Marital problems. Marriage in the United States now depends primarily on the personalities the spouses bring to it. Their personalities are shaped largely by their parents and by the marital modes to which they have been exposed, modes that often do not serve or suit a younger generation of newlyweds. From these circumstances, plus the greatly prolonged duration of the average marriage, derive some specific burdens of marriage in current industrial societies.

Whether the prevalence of marital maladjustment

is absolutely greater or only proportionally so compared to other periods is uncertain. Because the marriage now depends so greatly on the partners' personalities, the high prevalence of individual emotional maladjustment must be taken into account. If every 10th person spends some time in a mental hospital and if the prevalence of symptomatic personal maladjustment is still higher, marital adjustment, which depends so largely on personality factors, obviously carries a commensurate incidence of instability. Of course, marriage can also lend support and stability to an unstable partner. But the doubling of the marriage-life span also requires that the marital relationship be adaptable to more stages and to the challenges of longer lives.

Counseling. Because marital and familial maladjustment tends to be so encapsulated, the parents must seek help actively outside the family. In extended family systems, remedial influences may have arisen spontaneously from within the group through the efforts or the mere presence of one or more of the other adults. In this way the marital problem as such may have been contained and never have become quasipublic and statistical.

From the clinical standpoint, a marriage should be evaluated as a singular undertaking of two people. It should be examined in the contexts of their respective personalities and motivations for marriage and family and of the family they have already created. Their sociocultural milieu must be taken into account, and their coalition evaluated according to the class-specific modes of marital interaction.

Although a marriage between two disturbed partners can be satisfactory to them, this does not ensure a good prognosis for a healthy family. Furthermore, a marital coalition adequate for the nurturance of a few children may deteriorate if the family enlarges every year. Family planning through contraceptive control, to avoid offspring, to plan and space them, or to limit family size, is therefore an essential element of marital counseling and health care and of preventive psychiatry.

Premarital sexual activity. Premarital and extramarital sexual intercourse is difficult to assess statistically and cannot be discussed meaningfully as a single phenomenon. In particular, these practices must not be confused with morality, as societies that permit complete freedom of sexual activity after puberty are no less stable or less successful in living up to their cultural norms and preserving their continuity. The same is true of societies that condone extramarital sexual activity implicitly or explicitly.

The changes in premarital sexual activity in this society may be less marked in practice than are the attitudes toward such practice. Young people have gained freedom in recent decades to know and talk about sexual matters; they also expect tolerance with regard to their activities. This has led to the

present day demand of adolescents for their elders to take an open and nondefensive stand about rules and guidelines for sexual behavior outside marriage. There are serious advocates of complete license in this respect, and there are equally serious advocates of Victorian rules of behavior and thought.

The physician, however, should not take positions of generalities. When called on to advise or educate on matters of sex and marriage, it is incumbent upon him to inform about sexual matters and reproductive control, but it is also incumbent upon him to consider to whom he is talking and why. The patient's health needs, his or her life situation, and the capacity of the individual or couple for mature relationships, be the goal marriage or not, should concern the physician, who must be especially aware in this part of his work that the patient is apt to attribute to him a parental role. He must use such transference elements for the welfare of his patients in these emotionally charged instances just as skillfully as in any other facet of doctor-patient interactions.

Clinically, there is no evidence that premarital sexual relationships either promote or detract from successful marital adjustment. However, one reason for early marriage seems to be the desire for legitimate sexual union, even though emotional and socioeconomic independence may not have been achieved by the couple. This can create special problems if they become parents while still dependent upon others; also they may not be as mature and certain in their identities as they might be a few years later, when they might seek different partners.

Divorce. Divorce is popularly considered a kind of barometer of marital and societal stability, but divorce, too, must be understood in appropriate context. Divorce as a social phenomenon is susceptible to customs and legalistic vogues and to changes in the law, and it is also subject to religious codes. It is fashionable to point out that the divorce rate in this country has tripled in this century from 0.7 to 2.2 per 1,000 population and that the number of divorces has risen more than 7-fold. But these figures must be considered in the light of the changed basis for marriage, the modern risks to marital stability, and the freer attitudes toward the dissolution of marriages so beset by problems and suffering that present day counseling and therapeutic agencies find them beyond salvage.

In particular, the marriage counselor must examine critically a common rationalization designed to avoid divorce for the sake of the children. Children's needs and how they are served by a particular marital pair must be carefully assessed, without assuming a priori that two parents under the same roof are better than one. In the past a very disturbed marriage may have been continued because there was no avenue open to dissolve it (except through desertion), and economics often dictated its continu-

ance. Even today severe economic liabilities are usually imposed upon the divorcing parties by circumstances, or by the court, or by both.

The peak divorce rate in the United States of 3.5 per 1,000 occurred in 1945, when many hastily undertaken war marriages were dissolved, often by spouses whose life together could be counted in days or months. But, from the over-all statistical standpoint, the divorce risk time has doubled because, with an increased life expectancy in this century from 47 to 70 years, the duration of marriages (over 90 per cent of which take place before the age of 30) has more than doubled. The tripling of the divorce rate for the population represents an increment of between 30 per cent and 50 per cent if the rate is corrected for risk. The lowering of the average marriage age requires a further correction, so that the properly corrected rate increase is about one-third, which is quite different from the uncorrected figure of thrice the gross rate. Considering that 10 per cent of the population will require temporary psychiatric hospital care and that most but not all divorces involve one or two emotionally unstable partners, the present divorce rate is far from commensurate with the estimated prevalence of emotionally disturbed individuals.

Family Structure and Dynamics

In this and the following sections, the term "family" refers to the Western nuclear family, the isolated family of industrial society, unless otherwise specified.

From the sociodynamic standpoint, the family is a small group to which most small group dynamics apply, but it is also a very special group. The special group features pertain to the family's biosocial evolution in a particular culture and to its axial divisions into two generations and two sexes. These axes are important psychological and behavioral boundaries. The parents form the generation that leads, and they are implicitly obligated to relate sexually to each other. Sexual relations, however, are interdicted to all other members by the archetype of all taboos, that against incest. The generation of offspring follows and learns from the parents as gender-typical models.

As a group, the family moves from the parental dyad to a triad and larger group and later contracts again. Because the family is divided into two generations, each child's relationships to the parents is to some degree exclusive and unique and can be represented by an inverted triangle. The family consists of a series of overlapping triangles, each child forming a triangle with the parents, and these triangular relationships are not identical. It cannot be overemphasized that no child lives in the same family as his siblings in a dynamic sense, sometimes tangibly so because of changing family fortunes. Even identical

twins are ascribed different roles and characteristics by parents, by siblings, and eventually by themselves, so that each has different relationships with the parents and with the parental unit.

The family as a whole also constitutes a structural and functional unit. It has already been pointed out that one important task of the marriage consists in mastering the family's evolutionary transitions or crises. Besides the arrival of children, such critical phases include each child's oedipal phase, school beginnings, puberty, adolescence, and eventual emancipation as he leaves his family of origin physically and emotionally. Adversities, such as illnesses or economic or political misfortunes, may produce other crises and even temporary or permanent separations.

These evolutionary crises can also be viewed as a succession of separations, which all family members must learn to master. These separations can be tangible or intangible; that is, they may be on only an emotional plane, as when a child in early adolescence withdraws from closeness to parents. The evolutionary expansion of the family also involves issues of emotional separation and lessened dependency gratifications for the older members in the family. Family life, therefore, requires the capacity to forego individual gratifications for the sake of the group, whose cohesion depends on the example being set by the parents' foregoing some degree of their individuality and certain gratifications for the marital coalition and for the family. Each evolutionary step or crisis results in a new equilibrium and realignment of the family's emotional forces, and sometimes this leads to role changes and different task distributions.

Role divisions. The image of a strong authoritarian patriarchy of the Victorian age has been overdrawn, but it cannot work in modern democratic society. Compared to the Victorian prototype, the father in present day America has weakened, but more in appearance than in substance. Typically, the father's role is still that of the leader; his activities, his productivity, and his education determine the position of the family in the community and larger society, and these same factors also correlate with the character of the marital coalition. He provides the instrumental model of how things are done in society in matters of acquisition and survival. It is true that he can be pushed by his spouse's ambitions or even be overshadowed by her accomplishments in all these respects, but such a family may pay a price in suffering, disturbance, and pathology. The fact that the father's activities today occur mostly away from home, unshared and unobserved by the family, is a disadvantage.

The mother's primary role concerns the affective life of the family, and she also tends to its biological needs in health and sickness. Her role is expressive in that she not only tends to affective needs but identifies them and helps the children to learn about and

understand feelings and, therefore, is more responsible for their self-expressive communication. She also guides the child toward self-awareness. This is distinct from instrumental communication—how to get things done—which is more the father's domain.

These divisions are not absolute; they only indicate the dominant role of each parent. However, it must be appreciated that the mother's ability to help a child gain self-awareness and body consciousness and perceive and establish boundaries between himself and the world outside him is more crucial than the father's ability to do this, whereas the father's role as a leader and activator in matters of communal relationships is more important to the family than the mother's social competence and instrumental skills outside the home.

These role divisions are not only important for reasons of example but also essential in the children's acquisition of communicative skills. For instance, a father working away from home cannot be relied on to teach about intimate feelings in a detailed way, but he can bring to this and other family tasks a perspective that a mother, harassed by the demands of young children throughout the day, cannot maintain around the clock.

Parental role divisions should be flexible and complementary rather than fixed because, in crises, role complementarity may be essential, and temporary role reversal may even be necessary. Permanent role reversal of the spouses occurs, too. It may be mutually satisfactory to the parents, but it provides offspring with unsuitable models for their future life in society. Parental role reversals are particularly disadvantageous to the child if the reversal is covert but desired by both parents. Parents must provide gender-typical role models that are in harmony with the larger society in which they live, lest the child fail to acquire and incorporate role attributes and expectations of himself that have utility when he moves into the community.

Family structure and personality development.

Dynamically, the triangular structure of the family is epitomized by the oedipal phase of each child. Its adequate and appropriate resolution, which determines important salients of the child's psychic structure, depends more on the family structure and behavior than on biological determinants, as postulated by Freud. This appears to be true of all phases of psychosocial development, although parental attitudes and behavior are both reactive and interactive with the child, so that a child's equipment at birth, his temperament, and the parents' capacity to cope with infantile needs all coincide to establish the family's interactional patterns. From these patterns derive much of what the child sees and observes in terms of what kind of people his parents are—indeed, how they are human. Personality development, proceeding through identifications and imitations, depends as much on the parents' individual

characteristics as on their correlated marital and familial interactive behavior. The child observes and absorbs the defensive modes of those around him, and in this way secondary processes are acquired from familial examples and interaction.

After a child has learned body awareness and body management, including the correlated communicative facility, his relational learning begins. The task for the family is to help each child establish his place in the family and to make him feel sufficiently secure in it so that he can begin to move beyond the family circle without undue anxiety. To attain this place of nearly equal emotional distance from both parents, not only must he master body competence and competence in feeding, clothing, and toileting himself, but he has to master the oedipal issues of desexualizing his close primary object relations to his parents. Only then can he turn to peers as an increasingly important source of relationships. This step, in one sense the internalization of the incest taboo, the family must accomplish with him. The family accomplishes much of this not only nonverbally but almost unconsciously. The personalities, especially the degree of security in sexual identity that the parents bring to their union, and their coalition are more crucial to this task than in any other phase of family life, most of which can be more explicit and verbally directed.

Further personality development of the child will be less directly dependent on family structure and dynamics. But in subtle and not so subtle ways, the oedipal issues are relived in adolescence in terms of dependence-independence issues. These problems begin with the internal imbalances of puberty and continue into the prolonged path toward heterosexual competence and personal identity. The parental models play a role during this phase, often as an antipodal fulcrum for the offspring. To achieve a workable ego integration and identity, the offspring must be able to overcome his negativistic stances, which serve for separation from his elders but do not serve in themselves the reintegration of an independent and inwardly directed personality. If the antipodal position is very ambivalent and remains emotionally charged, it may become fixed. The child then remains partially identified with a parent he also rejects, a shaky foundation for ego integration and ego ideal.

Family Functions

Although it is artificial to separate structure, relationships, and functions, clarity may be served by the different emphasis of the sections. Indeed, the formation of a family structure is one of its inherent functions for its own sake, but it is also an implicit charge from the larger community. Society expects the family to prepare children for their lives as adults in the wider community, enabling them, in turn, to procreate and form their own families. Procreation is essential to the survival of any species, but the hu-

man species must also teach its heritage and thus ensure its continuity and future development. The family as the basic sociocultural unit is the embryo of social organization, and the parents are the sociocultural gametes.

The biological heritage demands a set of vital family tasks to be performed for the infant, such as feeding, sanitation, and teaching him body management and the utilization of survival tools. All this animals do for their young, and social organization is also a characteristic way of life of many species. For the human race, another dimension is added through the development of the culture-typical symbols and their utility, not only in the survival tasks but in planning for the future through an understanding of one's individual past and the group's collective past. Moreover, the symbolic communication among humans does not require physical proximity of the communicators in time or space, a prerequisite to communication among animals.

For the purpose of discussion, family functions will be separated as follows: (1) marital, (2) nurturant, (3) relational, (4) communicative, (5) emancipative, and (6) recuperative—keeping in mind that in vivo they all overlap and to some extent are continuous. Also, all except the marital interaction itself involve educational tasks, even though formal education is assigned to extrafamilial institutions in many industrial and other societies.

Marital functions. Marriage must serve the respective needs and satisfactions of the spouses and enable them to effect an appropriate family constellation in order to fulfill their tasks. Beyond the familial obligations, the marital partners must jointly prepare to renounce their close ties to their children when they are ready to emancipate themselves physically and emotionally from the family. The family ultimately becomes a dyad again and must turn its concerns from productive engagement in the community to issues of retirement and the concomitant aging processes.

Nurturant functions. The nurturant functions of the family encompass more than nursing and food supply, although these are basic at first. Beyond nursing, there are the other forms of physical care that the helpless infant needs. Their performance requires the mother's motivation and some degree of security on her part in performing these tasks. This security derives from her quasi-instinctual propensity for mothering, coupled with the almost symbiotic union with the newborn, such as the mutual and simultaneous relief of the baby's hunger and the mother's breast turgor, and from the support of her spouse and other family members, if any. The less specific nurturant activities of the mother continue throughout the life of the family. Eating together as a family at least once a day is not only a caloric ritual but a significant landmark in family life for communication, learning, interacting as a group, and relaxing together.

The psychological and symbolic aspects and overtones of nursing and feeding grow from, and with, the earliest mother-infant interaction. Here the infant acquires his initial trust in his human environment. Because the entire family is involved, their interaction with the mother-infant unit determines much of the nursing atmosphere. The broader nurturant tasks concern almost every aspect of the young child's development as he acquires body awareness and learns body management, sphincter competence, and self-care with regard to feeding and clothing. All these myriad activities—feeding with its symbolic significance, caring for the baby, helping the child to walk and to talk, getting things he cannot reach, supplying him with appropriate visual, auditory, and kinesthetic experiences—can at times be carried out by any family member or by other substitutes.

Relational functions

Weaning. Weaning is part of nurturing but implies more than withdrawing bottle or breast. The intricate physical closeness with the mother must be weaned, and an essentially nonphysical intimacy must be established with all family members. Weaning involves still more, in that both the process of weaning and its accomplishment are foundation stones in the acquisition of ego boundaries. In reverse, a mother may fail to wean a baby adequately and at the appropriate age because her ego boundaries are blurred and because she overidentifies with the infant. She also violates the generation boundary. In all these functions the mother plays the dominant role, but the entire family atmosphere and interaction are also crucial. For instance, parents already locked in an energy-consuming struggle with each other or with one child will necessarily neglect another child proportionally. It should be noted in passing that in terms of ultimate mental health, the underattended child may fare better than the overinvolved one.

Weaning, the cessation of sucking in the narrow sense, has important relational implications as the prototype of a succession of separation crises that characterize personal development and family life evolution. Nurturant competence on the part of the parents implies not only providing for needs and their satisfaction but also the capacity to frustrate and deny the child without provoking undue feelings of rejection and without undermining his natural propensity to grow and master problems, often painful problems. When frustrated or punished, the child may find his anger and hostility quite overwhelming, and he may lose faith in a parent temporarily. Nurturant and weaning competence in the family teaches the child that his temper tantrum does not overwhelm others in the family, and that he is separate but not alone. In reverse, a parent's anger and frustration with a child teaches him the limits of his provocative power and is another essential lesson in

grasping limits between himself and others and in establishing his own ego boundaries. Here the parental coalition counts: ideally, the uninvolved and nonangry spouse supports both the upset parent and the child.

Mastery of separation can be defined as the child's experiencing the pain of acute loss of good feeling toward, or of dissatisfaction with, another significant person, the parent, without losing faith and trust in the continuity of the relationship and the ultimate restoration of good feeling. Through these experiences he also learns and grows, becoming more able to avoid the same impasse and less vulnerable to and threatened by subsequent separations or emotional distance from others. This mastery must be facilitated by the opportunity to observe, imitate, and eventually internalize how other family members cope with frustration and this kind of separation anxiety.

The relational issues involved in the feeding and weaning experiences culminate in each child's oedipal phase. Its successful passage includes the central issue of effecting the incest taboo as a rather unconsciously directed inhibitory force within the child and within the family. Conscious incestuous preoccupations beyond the oedipal phase interfere with subsequent successful personality integration and growth, especially in adolescence. The child's omnipotent sense of exclusive relationship with the mother must be curbed and frustrated, enabling the child to wish to grow up like the same-sex parent and to relate to both parents as individuals and as a unit.

Peer group relationships. After the child has been helped to find his place in the family, permitting him to feel comfortable and safe in intrafamilial relationships, his relational learning turns to peer groups. Here the familial guidance becomes more distant and indirect, but familial facilitation and support of peer relationships are as essential as restraint against undue familial intrusion into peer activities. After 6 or 7, the child's relational learning depends increasingly on extrafamilial examples and on the family's social activities with relatives and friends.

Not only are the culture-typical distance and closeness to various people in differing situations learned that way, but extrafamilial persons are important as alternate figures for imitation and identification. Such experiences complement the parents' unique examples as members of their gender and their society and provide alternate or corrective models for parental shortcomings as people. Even if such shortcomings are not severe, teenagers often find their friends' parents or other adults superior and preferable as examples to follow in the service of emotional separation from the family.

Parents and the family as a whole must be able to tolerate such disloyalties, lest the emancipating adolescent bear an undue degree of guilt, burdening him with an intense conflict between his needs and

society's (that is, his peer group's) demands to be an individual on the one hand, and parental demands to conform to their standards on the other. Such an impasse may occur because of his inner needs or because of parental resistance to his independence, or both. The parents' respective values and expectations for their offspring must be in sufficient harmony so that the child can integrate parental objectives and standards and parents and children must reconcile these values and goals with the realities both of the child's capacities and of the community in which they live or wish to live.

Communicative functions. The central element in the family's educative mission concerns communicative competence. Talking with the child about his earliest internal and external experiences is essential to his beginning to talk and to communicate meaningfully. What he says and what is said to him must be meaningful to himself and to others so that through such sharing he comes to rely on the utility and consistency of language to express himself and to impress others. Only through language and the symbols basic to it does body awareness become body knowledge, and only through language can the basic trust of the mother-infant relationship be reinforced and broadened to include other family members and people outside the family. Without language (or equivalent symbols), prediction and a grasp of the future are almost impossible. For instance, only by very rigid timing could a child feel assured that he will be fed when hungry. Language allows for flexibility, such as, "supper will be late," or "after your bath tonight instead of before."

Familial communication must, of course, be related to the communication styles and symbol usages of the family's community. It must be appreciated that language plays a role in personality and concept formation beyond its communicative utility. Language reflects the culture's conceptual heritage and determines thought and concept organization across the generations.

The jargon of any younger generation combines elements of both the emancipating striving for separateness and of changes in language and culture. In some immigrant families special problems arise because school age children often surpass their parents in vocabulary and linguistic mastery, depriving both generations of certain communicative dimensions.

Emancipative functions. The ultimate goal for each child is to grow up and take his place as a full-fledged member in the society into which his family has placed him. In Western industrialized society this usually means that the offspring must attain physical, emotional, and economic independence from his family, being motivated and able to originate his own family.

In other societies the emancipative tasks may not be as stringent and extensive, but the family still

serves to guide the child toward the position society expects him to occupy as an adult. The process of emancipation of each child demands a compensatory reequilibration of the family after each departure, until the spouses return to a dyadic equilibrium, free to enjoy parental prerogatives as grandparents without the continuing responsibilities of the nuclear family. Obviously, each step toward emancipation poses the recurrent issue of separation, until it is final and definitive.

The degree of mastery of the earlier and more limited separations—beginning with weaning and later the beginning of school, separate vacations, and possible hospitalizations of members—indicates and to some extent determines the ease or difficulty experienced by the family when a child leaves for college, to get married, for military service, etc.

But geographic separation is only a part of the issues to be mastered; more important are the emotional components, the sense of loss experienced by all involved, and the inner capacity of each member and the capacity of the family as a group to do the work of mourning appropriately without becoming pathologically depressed. The departing member must accomplish this alone or with his spouse; the remaining family group can work it out together, the parents demonstrating appropriate mourning, faith in everybody's ability to master separation, and faith in the continuity of life.

The modern family is handicapped with regard to total separation experiences, as the death of a parent or child within the life span of the nuclear family is now rare, whereas it would have been rather usual only 50 years ago. Often now the four grandparents are still living at the time when a young adult emancipates himself from his family. And grandparents often live at a distance, so that the impact of their deaths on the nuclear family does not carry the immediacy and intensity of the permanent loss of a regular participant in family life. The time when the first child leaves may be the first occasion for all family members to mourn together, in contrast to the experience of a youngster of earlier generations, who usually would have shared mourning with his family incident to the death of a close relative.

Family bonds continue, of course, beyond the emancipation of the young. Rejoining one's family temporarily is a mutually enjoyable and relaxing experience, provided the family has done its tasks well. Opportunities for mutual support are also likely to arise after parents have become grandparents.

Recuperative functions. The family must provide for the relaxation of its members, relaxation of manners and behavior and even of defenses essential to interaction in the community. Most mothers are familiar with the need of an elementary school child for strenuous physical activity, even for a fight on his return from school, and the home must serve as a

controlling environment for such socially nonadaptive, possibly regressive, relaxation.

In the family circle parents shed formal attire, actually and symbolically. If a man's house is his castle, his family is the one group in which he can be king or at least president and in which he can also exhibit dependency needs. For such mundane reasons alone, the family might have to be invented if it did not exist, as no other living arrangements could provide for so many individuals these opportunities to forego formal behavior and recover energy for the work in the community which requires more formal and defensive interpersonal demeanor.

To some degree the family also permits its members to engage in creative or other activities that afford relief by contrast with the monotony of many jobs. By setting limits on relaxing activities, the family as a group also demands and teaches impulse control, in games, for instance, and all members may have to defer individual hobbies to family group activities at times. Children experience discipline in this way as with other frustrating experiences, first as outer control and eventually as inner restraint.

Finally, if the family is so burdened by its own tasks that relaxation and enjoyment as a group become jeopardized—either because of emotional conflicts and ill health or because its size overtaxes its emotional, nurtural, educational, or tangible resources and reserves—indications for family limitation and for outside assistance with family tasks are at hand.

Family Pathology

Psychiatric entities with a familial incidence based on chromosomal and inborn defects, whether hereditary or not, will not be considered here. Correlations between family pathology and psychiatric syndromes comprise all the many levels of human and social integration, and the conceptualization of these processes is difficult and complex. At this time there is much need for further clinical investigation and for standardization of conceptual terminology. Here, correlations among family disorders, psychopathology, and psychiatric syndromes will be outlined only in general terms, relating these phenomena to deficiencies and difficulties in the family's task performances, including the failure to evolve a workable structure.

Broken families. Broken families are the grossest but not necessarily the psychiatrically most devastating form of family pathology. Broken families are disproportionately frequent in the backgrounds of sociopaths, unmarried mothers, and schizophrenics, regardless of whether the fracture is through death, desertion, or divorce.

Family deficiencies

Parental psychoses and neuroses. Family deficiencies cover a wide range. Intrapersonal parental inadequacies form one large category. For instance,

severe immaturity may lead one spouse to seek a dependent position in the family, akin to that of an offspring. Such a spouse expects a parent role of the partner or even of a child. Beyond this, almost any form of neurosis or psychosis in one parent is apt to produce a defective parental coalition, which in turn will handicap the nurturant and enculturating tasks on which the children depend. Parents with severe hysterical or obsessional or other neurotic characteristics are apt to produce offspring with like defensive structure if not symptoms.

Mental inadequacies. Mental subnormality tends to run in families, apart from genetic factors. Below certain intelligence levels, parental functioning, especially the communicative performance, does not suffice to accomplish the enculturation of offspring. Educational inadequacies and inferior social position in a given subculture can also result in ineffectual family structure and dynamics, especially if the family belongs to a group against which the surrounding community discriminates actively.

Inadequate gender models. Inability or failure of a parent to serve adequately as a gender model appropriate to the larger society leads to increased developmental vicissitudes, especially for the child of the same sex. This is even more true if, as is often the case, the posture of such a parent is further weakened and undermined by the mate's critical and even contemptuous attitudes. The insecure gender identity of a parent predisposes the same-sex child to gender uncertainty and confusion, leading to social ineptness or the development of perversions or schizophrenia.

Need for an extended family. Another form of family pathology peculiar to the nuclear family can be viewed as a surreptitious need for an extended family system. This occurs overtly or covertly when one parent or both remain primarily attached to and dependent on their parents or a parental substitute, and the center of gravity for authority, decision making, and emotional investment rests outside the nuclear family group. This distorts family structure and functions, especially if both parents feel primarily beholden to their respective families of origin, and no workable coalition for the younger family becomes established. An extended family system is quite workable with differential role assignments across three generations, but it is damaging to a nuclear family that intends or aspires to such designation and that geographically lives as a nuclear family.

Overinvestment in children. Parental overinvestment in the achievement of children, especially the parents' social prestige aspirations, is related to the development of depression in offspring. Such parental attitudes are introjected, and they predispose the child to intense ambivalence and a sense of being loved and worthy only on the basis of superior performance and achievement. Punitive attitudes toward the self supervene when failure in terms of the internalized overstringent expectations occurs.

Schismatic and skewed families. Probably more pathogenic than actual parental separation is family schism. Here, the family is divided overtly or covertly into warring camps, usually because of chronic conflict and strife between the parents. The children are forced to take sides, to the detriment of their personality development and integration. This type of family pathology is found in the background of schizophrenic patients.

Another form of family pathology related to schizophrenia is the skewed family, when a dyad other than the parental one dominates the group emotionally and often tangibly. A skewed marital relationship is different; here, one spouse expects the other to be a parent to him or her, or one disturbed parent dominates the other and family life absolutely and rigidly. Such a marital coalition preempts parental functions and emotional resources, and the children's affective and psychological needs are neglected.

In both schismatic and skewed families, violations of the generation boundary abound, and in both, the intense relationship between one parent and one child may have seductive and incestuous components, an additional violation of sex-role requisites if not of the incest taboo.

Overt incest is evidence of gross parental psychopathology and of defective family structure. Father-daughter incest is commonest, but both parents are psychologically involved, since incest often bespeaks a tenuous equilibrium in a family that seeks to avoid overt disintegration. The involved daughter has often assumed many parental functions, while the parents maintain a facade of role competence. The family often breaks up after incest is brought out into the open, usually by the involved child.

Faulty communication. Aberrant communication in the family is a common psychiatric finding. Although usually secondary to parental psychopathology, notably thought disorders, faulty communication also builds up a pathogenic autonomy of its own. Young children learn the defective communication modes, distorting their linguistic development, perception, and concept formation. If communication is confusing within the family and ineffectual as expressive or instrumental tools, children are deprived of a critical socializing instrument outside the family. They may never gain basic faith in and reliance on the utility of communication. The seeds of autism may be sown in this way. Severely amorphous or fragmented methods of communicating have been found among families of schizophrenic patients.

Learned aberrations. Parental examples of paralogic thinking and of fear and mistrust of their social environment affect offspring by creating confusion and anxiety, and children may internalize the faulty ideation and the mistrust of the world. This is the familial counterpart of Cameron's pseudocommunity, and paranoidal suspiciousness can be learned in this way.

Johnson and Szurek delineated another form of family pathology among sociopaths who carry out covert or overt needs or wishes of parents. The child's asocial behavior may express directly such propensities of a parent in exaggerated form; in other instances, the child behaves like a sociopathic parental collateral whom one parent secretly, or not so secretly, admires.

Clinical Evaluation

Besides the history of psychiatric disorders in the family, clinical assessment concerns family functions, but function and structure cannot be separated as neatly by the clinician as by the textbook writer. The observation of functioning and coping forces inferences about structure and vice versa. Just as the clinician can draw inferences about lung structure or pathology from breathing patterns, so also can he deduce on a statistical basis that chronic sociopathic behavior in an offspring, for instance, is related to structural and functional family defects.

Symptoms aside, the clinician seeks information about the basic elements of family structure, notably the maintenance of the generation boundary and the gender-linked role divisions and complementarities, and about the manner in which the family copes with its major tasks and functions. He pays special attention to their communication modes.

Diagnostic investigation and therapeutic influences overlap in the establishment of family diagnosis, as they do in psychiatry generally. This section will not deal with techniques of assessment but will only outline the referential framework for evaluation through family history and direct observation.

Information sources. Ideally, the individual histories and statements of all family members are combined and examined for congruent and contradictory data. These individual records are complemented by participant observation of the family as a group. There are many methods available for this, ranging from open-ended family interviews to more or less structured formats, including the possibility of having the family do specific tasks or tests together while being observed and, preferably, recorded.

The spouses. The referential framework begins with an examination of the marital relationships, the pertinent data concerning the spouses' respective backgrounds, their personal developments, educational levels, socioeconomic class positions, and the cultural and ideological value patterns of their respective families of origin. Significant discrepancies in these parameters should alert the examiner to potential conflict areas, and he should investigate the resolution of such discrepancies. For instance, he should investigate discrepancies with regard to religion, social class ambitions, desired family size, and rearing methods of and goals for the children.

Family structure. Data about family structure can be obtained through inquiries about living and

sleeping arrangements, activities of the family as a group and as part groups, role divisions incident to various family tasks, and the decision-making processes. As far as possible, these items should also be examined directly through group observations, as should the possible existence and nature of dominant dyads other than that of the parents. In observing the family as a group, the diagnostician gains impressions about the extent and methods of parental leadership, and whether it is united or not, that is, criteria about the effectiveness of the parental coalition and the integrity of generational division. Gender appropriateness in manners and in conversational content can be established impressionistically in family interviews, or inappropriate seductiveness can be documented, for example.

Family coping. This can be assessed by learning about crisis behavior. The normal crises of family evolution are important sources of understanding about the family's coping patterns, coping reserves, and coping deficiencies. Among such crises are possible resistance or reservation of the spouses' families to the marriage and how this was resolved; the first pregnancy; the original triad formation; subsequent pregnancies and births; economic misfortunes; deaths of relatives or friends. In psychiatric practice the examination often takes place in a crisis situation, such as that incident to the hospitalization of a family member as a mental patient.

Social network. The nature of the family's social network should be examined to establish social isolation or the nature of family relatedness within the community. The network must fit to some degree the class position and the patterns of the community and subculture of which the family is a part. The involvement with the spouses' families of origin and collaterals also must fit to some degree their cultural pattern, or conflict should be presumed and the resolution of it examined. A parent's intense attachment to either family of origin should alert the examiner to the possibility that a truly nuclear family has not been established.

The children. Evaluation of the children depends on their respective ages. Pediatric histories, including well child care data, may be the only source of information available outside the family. For older children, kindergarten and school adjustments, records from recreational agencies, and, when indicated, information from neighbors and friends as to the socialization of a child can be utilized. School phobias are a classic manifestation of deficient separation mastery in the family.

In families with older children, attention must be paid to their emancipating efforts and the parents' reactions to these. Adolescence, notoriously a family stage of uneasy truce in many respects, should be just that, a family dissolution process, at least on an emotional plane. Adolescents must experiment with greater independence, and each step carries a poten-

tial for disagreement and conflict for all concerned. Also, the adolescent's dissatisfaction with and opposition to parental standards are an intermittently necessary stance for him in his strivings for emotional distance and independence. Examining and evaluating the family with adolescent offspring are, therefore, especially difficult because of this evolutionary state of imbalance.

Intrafamilial communication. Here, recordings or films are essential if detailed analysis is to be attempted. But grossly or impressionistically, the clarity of communication or lack of it can also be seen and heard. Contradictory statements in the same verbal passage or discrepancies between verbal content and nonverbal communication may confuse rather than convey meaning or may have a double bind effect. Scapegoating of a member becomes readily apparent, as do ambivalences, such as the more or less covert condoning of a member's behavior that also constitutes the family's complaint. Careful analysis of verbal passages or special tests given singly or to the group will disclose thought disorders and ideational defects.

Tools. Questionnaires and schedules of family process items are available or can be composed for specific assessment modes, but in general they are ancillary diagnostic tools. They are most useful for the examiner who wants to standardize examinations for data-retrieving purposes, for research, or for didactic purposes. Their major value, therefore, rests with the organization of data and not with the information-gathering segment of clinical evaluation, which rests primarily with the clinician's skill and art.

Suggested Cross References

Additional material on normal sexual functioning can be found in Lief and Reed's section (Section 5.7) in this area. Family therapy is discussed by Ackerman and Kempster (Section 34.8) in Area G, on psychiatric treatment. For a further discussion of communication see Ruesch's section (Section 3.6). Family interaction as a determinant of psychopathology is also discussed in the sections that deal with specific psychi-

atric disorders such as Section 26.3 on homosexuality and Section 15.3 on the etiology of schizophrenia.

Chapter 5

Other Fundamental Topics

5.1 EPIDEMIOLOGY

PAUL V. LEMKAU, M.D.

GUIDO M. CROCETTI, B.Sc.

Definition

Epidemiology is the study of health conditions in a population in relation to any conceivable factors existing in or affecting that population which may influence the origin of the health state or affect its distribution in that population. The object of such study is to ameliorate any factors that contribute to ill health, to enhance any that contribute to health, and to draw generalizations from studies that can be applied to other populations to contribute to health in general. From the point of view of pure or basic science, the objective of the promotion of health is not essential to epidemiology. But, as a derivative of the public health movement, epidemiology has always had a large element of applied science in its conceptual base. In practice, the promotion of health and the alleviation of disease states are accepted as parts of its logic.

History

The origins of the science of epidemiology are very ancient. Probably the first discovery was the fact that disease tends to be a greater threat when the wastes of human living accumulate. The importance of human feces in the spread of disease probably followed this general but vague notion and led, as much as esthetic reasons, to the invention of sewers and other methods of waste disposal.

Mosaic laws. Certainly by the time it was possible to encode the Mosaic laws (about 1200 B. C.), a great deal of epidemiology was already known. Not all the Mosaic laws are interpretable in the light of modern medical science, and it is impossible to know what sort of logic, superstition, or magic underlay many of the dietary and other laws. Yet it is clear that the interdiction of pork could have had to do with a fear of trichinosis and other diseases and that the inter-

diction of shell fish may have had to do with gastrointestinal diseases or induced reactions to products of decomposition.

The rules regarding the handling of the sick and of corpses are easily seen to be related to the recognition of the contact transmission of disease and of the importance of fomites. Similarly, the laws regarding the management of lepers, whatever disease or diseases the Biblical term leprosy may have included, show a recognition of the transmissibility of disease from the sick to the healthy. Such notions were considered important enough to be incorporated into the highest level of law in the theocratic organization patterns of the Israelites of that time. Indeed, in almost all civilizations prior to the Renaissance, health and disease were very closely bound to the religious systems of the people.

Epidemic constitution. In addition to the more or less specific relationships implied in the Mosaic laws, used here as one of the earliest examples of applied epidemiology, there was much thought given to why waves of disease struck at particular times and intervals. These rather vague thoughts found expression in such terms as "epidemic constitution" into which were woven at different times and by different people ideas of the influence of climate and other cosmological factors. The name "malaria" (*mala aria* or bad air) is evidence of this, as is the propensity for keeping out the night air in malarious regions or the avoidance of low lying land in favor of higher areas for the building of summer homes.

This sort of nonspecific but nevertheless effective action based on epidemiological concepts perhaps reached its highest point in the famous Broad Street pump incident in London in 1854. At that time John Snow realized that cholera was being spread by water from a particular pump and prevented the use of that water by dismantling the pump, thereby retarding the epidemic.

Incidents that involved no recognition of any specific etiological factor but were nevertheless effective—Jenner's discovery of cowpox vaccination to prevent smallpox, for example—were accompanied by a great many ineffective actions. These are often forgotten in the congratulatory history of the successful ventures.

But during the same period useless fires were built in the streets to arrest plague, and as late as the 1950's swimming pools were emptied and public assemblies forbidden to prevent the spread of poliomyelitis, though both actions were ineffective.

Specificity. The next step in epidemiology came with improvement in diagnosis. The most important figure in this was Sydenham, who distinguished many illnesses in the 17th century. He recognized that such broad generalizations as the epidemic constitution could not deal equally well with all questions of disease spread; each disease might well have its own laws of spread and, by implication, of control. This is a concept too late applied to mental diseases. There is still tendency to talk of the prevention of mental illness, as though the prevention of paresis, pellagrous psychosis, various postencephalitic states, alcoholism, mongolism, depression, and schizophrenia were all the same.

Sydenham's work led to the recognition that specific illnesses required specific preventive measures and that the concepts "infectious disease" or "exanthems" were useless in prevention for the most part. The same lesson of specificity is only now being learned in psychiatry. Too often, prevention is dealt with in terms of broad generalizations, as though there were some panacea to be found that would deal with all the variety of mental diseases. In every case in which a mental illness has been prevented, a clear cut etiological factor related to a definable syndrome had been discovered. Witness the decline of syphilitic psychosis with the emergence of effective treatment for syphilis, the decline of pellagra with improvement in knowledge of nutrition, the decline in frequency of toxic delirium with the introduction of the sulfonamides and the antibiotics.

The discovery of the importance of bacteria in disease led to the development of the modern epidemiology, and this phase in the development of the science is only a few decades past its zenith. With the discovery of obligatory etiological agents—first bacteria and then viruses, Rickettsia, mycobacteria, and others—the development of the epidemiology of the "one overwhelming cause" took place. For a number of years concern was almost exclusively on etiology and the control of etiological agents, either directly or through immunological reactions. This era is still underway and is still of outstanding importance; witness the control of poliomyelitis in 1955 and the still more recent immunizing procedures against measles. From the psychiatric point of view, a good deal remains to be done in this branch of epidemiology; there are unsolved problems in encephalitis and rubella, for example, the solutions to which will contribute much to the prevention of some psychiatric syndromes.

Multifactorial etiology. The golden age of epidemiology just discussed did not solve all of the problems of epidemiology, however, and a new era of epidemiological study began with a familiar term in psychiatry,

"multifactorial etiology." During the golden age just described, epidemiology was mostly concerned with obligatory factors in disease, that is, the etiological agent in the absence of which no specific disease could occur. There could be no pneumococcal pneumonia without pneumococci, no leprosy without *Mycobacterium leprae*, no measles without the measles virus, no schistosomiasis without flukes, no syphilis without the spirochetes. These etiological agents, however, were not enough to explain all problems. There were always individuals in the population who were known to be infected but who did not become ill. There were always those who recovered while others died. And there were many diseases in which the model of infection did not fit the cases, notable among them being some arthritic conditions, arteriosclerosis, and, among the mental diseases, schizophrenia, depression, neurosis, alcoholism, and the character disorders.

These unsolved problems led, under the leadership of Dubos and others, to a renewed consideration of the host factors in disease, those factors within the individual that determined his vulnerability. The disease that precipitated much of this thinking was tuberculosis. In this disease, the obligatory cause, the mycobacterium, constitutes a smaller proportion of the total etiology than is the case in more acute diseases. But the other diseases listed above were also important in the development of this phase of epidemiological development. For the most part they are diseases for which no obligatory factor is as yet known. It is a matter, at present, of looking for all possible factors associated with the diseased state. Felix expressed the concept very economically by saying that schizophrenia was like tuberculosis without the mycobacterium entering the picture. Except for those mental illnesses known to have obligatory causes—and they are numerically small in proportion to the others—the epidemiology of the mental illnesses falls in the same category as the epidemiology of arthritis, coronary thrombosis, and arteriosclerosis.

Too often the accomplishments of the golden era of epidemiology for psychiatry are overlooked. The conquering of syphilis led to a decrease in psychiatric illness considerably greater than that in physical disease contributed by the prevention of poliomyelitis or measles. The antibiotics have tremendously reduced the psychiatric problem of toxic delirium. Furthermore, the control of infectious diseases has relieved much occasion for the emotional stress of grief in parents. The control of childhood fever has allowed a much higher proportion of children to be raised by their mothers than was the case earlier in human societies. The golden era of epidemiology contributed both directly and indirectly to mental health.

Study Methods

Diseases with obligatory causes. Epidemiological theory has been concerned in part with the way epidemics rise and fall and the periodicity of these waves

of illness. This part of epidemiological theory is concerned primarily with diseases with one overwhelming, obligatory cause.

The shape of the ascending epidemic curve depicting the proportion of a population affected by a disease over a period of time appears to depend primarily on such factors as the length of time between exposure and onset of disease for the particular illness under question and upon the method of transmission of the disease. The descending arm of the epidemiological curve depends on the exhaustion of the supply of susceptible persons in the population. Both ends of the curve depend, also, on the prior history of the disease in the population, the type of immunity resulting from having the disease, and any immunizing measures that may have been used. It is relatively easy to study the shape of epidemic curves by animal experiments, and it is also helpful to express the various possible shapes of curves in mathematical form. Particular shapes of curves are typical for certain groups of illnesses, and the epidemic curve may lead to the determination of the diagnosis in some epidemics and can lead to information useful in identifying the obligatory etiological agent. Statistical devices are most useful in determining the significance of epidemiological data; that is, statistical tools allow estimation as to whether changes are due to chance or are related to a patterned sequence of events.

These experimental and mathematical methods have been useful in diseases that occur in waves and then disappear or reach a low ebb of sporadic occurrence. They have thus far been less helpful in the study of diseases that vary little in their rates over time or that do not result in death or recovery within a relatively short period.

Chronic diseases. Chronic diseases require other methods of study, particularly when no obligatory etiological factor is known. Changes in rate of occurrence are likely to be rather slow, making them hard to interpret, particularly since medical science is likely to have changed in quality of diagnosis and treatment while any change in rate has been occurring. This is particularly true when the causative factor has to act over a long period of time to produce its effect.

The best example of this kind of problem is the association between cigarette smoking and lung cancer. Such an association could not be found until the diagnosis of lung cancer could be made quickly and accurately and until sociological methods to determine who smoked in the population had also become available. Etiology of lung cancer as related to tobacco tars probably could not have been discovered without the development of surgery that offered the possibility for cure; it is hard to arouse interest in a disease for which there is no cure. The epidemiological success had to await developments in several other areas of medicine.

Life table. The tool most useful in studies of chronic illnesses for which no obligatory cause is known is the

life table. Essentially the life table is a composite of the experience of a group of people who share certain common factors considered to be related to a pathological process, in contrast to a group without these factors.

For many diseases the end point of the life table is death; in other diseases the end is a form of disability. In psychiatry the measure is often hospitalization, considered to be a measure of behavior disorder in that society will no longer tolerate the sick person in its midst. Some have termed this measure the point of social or productive death of the individual. Although the concept has certain advantages for dealing with psychiatric illnesses, the tolerance of societies does not stay constant, and advances in treatment may result in improved behavior without affecting the underlying disease process. Nevertheless, the life table method presents many still unexploited possibilities for the study of psychiatric illnesses and of factors in mental health.

Many mathematical tools have been developed for the interpretation of life table information. A modern and as yet uncompleted experiment dealing with what is essentially life table methods is the work on the relationship between diet and arteriosclerosis.

Diseases without known etiological factors. The life table method is also applicable in studying illness states in which no etiological factor can be postulated. Various sorts of events occurring in peoples' lives can be used as the basis for forming contrasting groups, which can then be followed to some other event, such as the appearance of disease, social or productive death, or death itself. The method can be applied with some greater risks to retrospective data. Plummer and Hinkle used it, for example, in the study of the relation of ill health to certain social situations in female telephone employees and in relating ill health to events in the lives of migratory students. The studies of the types of families producing schizophrenic children are essentially life table studies, though the numbers reported are far too small to allow the use of the available mathematical tools for tests of significance. Although the life table method has not been applied rigorously enough to allow genuine evaluation, it is the concept that underlies most of the thinking relating childhood behavior disorder to later disease or health. At the present time the most rigorous studies tend toward a negative relationship, though the end of the story is not yet clear.

Diseases with multiple etiology. It is clear that the life table method allows the testing of a very wide range of possible relationships between events and what follows them. In individual cases, the method was introduced by Adolf Meyer as the life chart. Lorr and others have worked out various ways of evaluating behavior at successive points in time so that intervening events may be related to later behavior. From this sort of study of the lives of individuals, hypotheses arise that can then be tested by life table methods.

How to quantify experiential events and the status of illness and health remains a persistent problem greatly deterring the testing of hypotheses in the area of psychiatry but at the same time offering inviting vistas for research.

Mental diseases. Reed has voiced many of the problems in the application of epidemiological methods to mental diseases. His conclusion is that the methods of epidemiology are applicable to psychiatric diseases, provided the data can be properly quantified. By this he means that diagnosis must be replicable, if not valid, and that life events involved in hypothesis testing must be somewhat quantifiable.

These desiderata are important, but helpful concepts may be developed through work done before they are fully met. Snow controlled cholera before he knew why the action he took worked, and he did it in the absence of any mathematical controls. Psychiatry has an equal basis for hoping that its studies may lead to serendipitous discoveries of a helpful sort before it is able to reach the level of excellence of data that will allow the application of the most highly developed epidemiological theory and methodology. Along with mistakenly building fires in the streets, some other kind of removal of the handle of the Broad Street pump may be encountered.

Action cannot be delayed at many points. The clear cut proof that a kind of retardation is associated with the absence of an enzyme necessary in the metabolism of phenylalanine logically leads to the testing of all infants and the inauguration of special diets for those lacking the essential enzyme. Meanwhile, the as yet unproved assumption that children deprived of a broad preschool experience contribute a high proportion of the mildly mentally retarded cannot be neglected. Preschool education for underprivileged children like that going forward under the antipoverty program in the United States, may prove to be as ill founded as building fires in the streets was for controlling plague. Yet there must be an effort to control the apparent deficiency in mental health, and preschool education is the best way presently known to accomplish the task. Epidemiology does not insist on absolute proof of relationship. But it does help place some responsibilities for selection of methods and for marshaling available facts concerning actions taken to relieve the problems of the various mental illnesses.

Epidemiology of the Mental Illnesses

For the most part, the epidemiology of the mental illnesses is at a quite primitive level, particularly in regard to its most important problems—schizophrenia, depression, and the various neuroses. Depression and schizophrenia are better studied than the neuroses, probably largely because they are more reliably diagnosable, though they leave much to be desired in this area. Diagnosis of neuroses is far from reliable, that is, reproducible by equally qualified diagnosticians.

Studies of schizophrenia and depression have been largely descriptions of the prevalence of the illnesses in various populations and the comparison of the sick, by various characteristics, to the total population. Hypotheses have been based on such findings, but exceedingly few, if any, studies have been directed toward the testing of hypotheses. Leighton is in the process now of testing whether changing the social organization of a community will change its rate of symptoms of mental illnesses. This study is based on his earlier finding that less socially organized communities have a higher rate of symptomatology than better organized ones. This is one of the first attempts to test an hypothesis after formulating it on the basis of prior research into the distribution of symptoms. It is similar to the preschool education program already mentioned except that the etiological concepts involved are much better supported by data in the Leighton research than in the necessarily far broader test of a less well documented hypothesis in the Head Start program.

Epidemics. The earliest publications on epidemiology of mental symptomatology had to do with reactions sweeping through populations in ways familiar from the study of epidemics of infectious diseases. In Italy around the 17th century an epidemic of very fast dancing ran through the country. The reaction was supposed to follow the bite of the tarantula, but it is clear that the need for this stimulus soon faded out, the reaction becoming psychogenic. The epidemic left its permanent mark in music, the tarantella form being that of a very fast dance.

William Sargant has continued the study of such epidemic psychological reactions, linking the tarantella with trance-like states appearing in every period of civilization, depicted on Greek vases and seen today in many religious sects, such as the dervishes and, in the United States, the snake handlers. Such reactions have not been well studied epidemiologically. It is not known, for example, what proportion of populations are actually involved or how many consciously put on an act while others are carried away by the various kinds of reactions. One of the best studied of such epidemics is one reported from Louisiana in 1939 (Schuler and Parenton, 1943). An excellent bibliography on ancient psychological epidemics appears in The Milbank Memorial Fund publication on epidemiology (Jastak and Whiteman, 1957).

Genetic illnesses. Perhaps the earliest modern studies of the epidemiology of mental illness were those of Luxenberger and Brugger in Germany, published about 1928. These studies were primarily designed to test hypotheses in the genetic area. A case of an illness was selected as a starting point, and all relatives of this case were then investigated as to the presence or absence of psychiatric illness. Another person who was not ill was also selected and matched with the case for certain characteristics. His rela-

tives were similarly traced and examined. The results of such studies gave not only the differential rates between the two basic groups but rates in specific, defined populations as well, the first such rates in the literature. Studies allowing similar conclusions were done in other places as well. The genetic aspects of these studies form a legitimate subject for epidemiological research, and they have continued, largely as twin studies, under the leadership of Kallmann.

Direct research in total populations. The next step in epidemiological studies was direct research in total populations to see what illness they had produced. Fairbank and Lemkau were leaders of groups in Baltimore and were probably the first to have skilled biostatisticians associated with them in such studies. Their group worked in the urban Eastern Health District of Baltimore; a companion group was working at the same time in a rural area of Williamson County, Tennessee.

The Baltimore group searched all available sources to find cases of psychiatric illness, from the mental hospitals to the police records to the records of social agencies. The cases were analyzed by geographic location, race, age, sex, and economic status. The Williamson County study was obliged to establish a diagnostic and treatment center in order to find and obtain diagnoses on cases, a technique later used by Leighton and his colleagues as well. The actual rates obtained in these various studies and others appear in this volume where the various illnesses are discussed (Area F).

Defined populations. Strömberg in Denmark began the study of defined populations. He used the total populations of relatively isolated islands for study, populations in which individuals who were ill could be traced. This research design was also used by Bremer in the study of an isolated fishing village in northern Norway. This study indicated for the first time that psychiatric symptomatology was actually exceedingly common. His figure was 25 per cent of the population, of which he studied each member personally.

Ødegaard defined his population for study in another manner—by whether or not they had carried out a certain action. He studied the rates of mental illnesses among Norwegians who had migrated to the United States as compared to family members who had remained in Norway, coming to the conclusion that those who migrated were at greater risk of mental illnesses than those who remained behind. In general, this conclusion has stood up rather well in the light of later findings, though other patterns of migration may provide different findings.

Eaton and Weil studied the Hutterites, a group defined by their religious beliefs and a kind of communal social organization. The group lives in northwestern United States and southwestern Canada and is highly inbred. The legend that this group had no mental dis-

ease was exploded by the study: the rates for schizophrenia were not markedly dissimilar from those in other populations, and depressions seemed more common among the Hutterites than in other populations.

Another method of defining a population was used by Gruenberg in his studies in New York State. He used an age limit, interviewing all people over 65 and establishing rates according to certain social and economic parameters.

Mental retardation. The epidemiological study of mental retardation began with a Scottish study of the early 1900's. The intelligence of a large number of children was evaluated by psychological tests; the state of mental retardation in adults was judged by social characteristics. The study probably missed very severely retarded cases, and its criteria for diagnoses left something to be desired. Nevertheless, this study represented a large step forward in methodology, and its main findings have often been replicated by others.

A more thorough, census type of study was attempted by Jastak in the 1950's but unfortunately resulted in few publications. It did tend to show that Lewis's finding of high rates of mental retardation in rural as compared to urban areas was less marked in the 1950's than it was earlier in England. Studies by others have thrown light on many technical problems in the study of the epidemiology of mental retardation. Imre is conducting a very thorough study of a rural area, profiting from the improved methodology now available.

Gruenberg surveyed a New York county, using teachers as case reporters. He found that, using this technique, his reporters tended to include a wide variety of behavior disorders as retarded cases, even though their psychological test scores were quite high indeed.

Problems encountered. In all these studies there are problems of definition of the illnesses counted, of severity of symptoms reached before a case is counted, of whose judgment is to be used if the case is not seen personally, and many others. There is also a problem of how to present the data. This matter has now reached a rather stable point; data are presented as incidence rates and prevalence rates. Incidence rate is that proportion of a population that becomes ill for the first time during a specified time interval, usually a year. Prevalence rate refers to the proportion of a population ill at any one period of time, regardless of time of onset. Prevalence rates may be given as of a single day or as the total number ill during a specified time, regardless of whether they were continuously sick throughout the period. In some studies it is assumed to be important to the future of the individual if he has ever been ill, and the figures are presented as cumulative, so that a prevalence rate not only includes those sick during a specific period but all those in the population who have been ill with a mental illness at any time and are still alive. Although these

conventions are often violated by workers reporting studies, strict adherence to them allows comparisons between studies that are otherwise impossible.

Studies of groups of patients. The analysis of groups of patients to find their characteristics was apparently begun by Esquirol about 1830, when he found a need to know what sort of people he was taking care of in his hospital. Studies of this sort are generally based on data gathered for official administrative reports, although more recently some have been done primarily for scientific purposes. Malzberg in New York and Dayton in Massachusetts have been most influential in the early period, and Kramer et al. represent more recent studies. The earlier types of studies are conveniently gathered in the books by Landis and Page and by Dayton as well as in Malzberg's numerous papers and books.

These studies have brought out such facts as the very high rate for senile psychosis in the 7th, 8th, and 9th decades of life; the variation in risk of the two sexes in the different mental illnesses; and the differences in rates of illnesses of various sorts in groups when analyzed by national origin, race, and so on.

Data on hospitalized patients have also been used to attempt to answer the question of whether the mental illnesses are increasing or decreasing in populations. For the most part, the results remain equivocal. Goldhamer and Marshall were, however, able to present data extending over the century from 1840 to 1940 and reached the conclusion that there had been no increase in severe mental illnesses in the young adult age group during that period. Their data suggest that there may have been an increase in psychoses of the senium, though they were unable to separate disease from social factors influencing hospitalization in this group to their own satisfaction.

Kramer introduced studies of cohorts of patients into psychiatric epidemiology. Patients of a particular age group are admitted during a particular period selected, and their fate over a period of years is determined. He has shown the outstanding differences in mental hospital retention rates for different mental illnesses and, perhaps more than any other worker, has demonstrated that there is a high rate of turnover of patients in psychiatric hospitals, even though there is at the same time a large residual population in which there is minimal movement.

Bahn, Gorwitz, and Miles have recently added statistics regarding out-patient services to those on in-patients. It is too early yet to have come to any secure findings in relation to the new source of patient service data. Thus far, the data indicate that services vary in amount furnished to various segments of the population, with the elderly and those of the lower social status groups receiving disproportionately low amounts of service. As the data collection methods mature, firmer as well as more detailed conclusions will undoubtedly be reached.

Hollingshead and Redlich have studied the type and

amount of psychiatric service available to persons of various socioeconomic groups. Their data tend to show that psychotherapy is offered far more often to more advantaged groups and that the low socioeconomic groups tend to be treated by means of physical methods—electroshock, drugs, and other forms of direct management. Furman, Sweat, and Crocetti found similar relationships in a study of out-patient services. Jaco, in a study of treatment practices in Texas, reached somewhat similar conclusions and dealt also with differences in availability of treatment in different racial groups—the “Anglos,” the Spanish Americans, and the Negroes of that society.

Psychiatric register. Material on in-patients and out-patients is presently being combined by means of a new technical device, the psychiatric register. It will not only allow much more prompt and accurate reporting of a far larger variety of cases receiving services by a variety of service units but will also allow, for the first time, the study of the psychiatric management of behavior disorders over long periods of time. This will solve one of the most vexing problems of longitudinal studies—the Scylla of the danger of retrospective studies being influenced by the state of the patient when the study is made and the Charybdis of having to wait a very long time to see how cases mature. While a relatively small amount of data can be preserved for each patient at each contact with a service, the register can be used as an index to existing case histories. With computer techniques, information can be very quickly analyzed and groups compared in an almost infinite variety of ways. The register technique will greatly facilitate some kinds of epidemiological research in the future.

The pattern on which registers are being developed has come to a considerable extent from the United Kingdom, where Brooke et al. have exploited the National Health Service's statistical data. Their interest has been, to a considerable extent, administrative. It is from their work that the United Kingdom projects a rate of psychiatric hospital beds of 1.8 per 1,000 for the future.

Lin's exhaustive and thorough studies in Taiwan have provided data for his review of psychiatric epidemiology, from which he concluded that approximately 1 per cent of populations are actively psychotic but that beds need be provided, at least in developing countries, for only one tenth of these. These figures stand in contrast to those of Pasamanick and Lemkau, who found approximately 10 per cent of the population seriously impaired by psychiatric symptomatology at any one time.

Studies based on symptom recording by patients. Alexander Leighton et al. conducted studies in a semi-rural agricultural, lumbering and fishing area known as Stirling County. Thomas Rennie et al. conducted similar studies in a defined area on the east side of Manhattan. In both studies, although the methods were different in detail, the basis of the data was inter-

views with a relatively small sample of the total population. Questions asked were usually designed to ascertain whether or not patients had symptoms that might be regarded as psychiatric or psychosomatic. The interviews were scored by psychiatrists as to whether or not the patient was ill and to what extent illness impaired his functioning. In general, the Leighton group exercised somewhat greater care in the scoring process than did the New York group. In neither study was any attempt made to establish specific psychiatric diagnoses.

Both studies reported high rates of symptoms in their populations, and the results of the two are so nearly alike that they can be presented together for the purpose here. Over-all, both found about 30 per cent of the population to be rather seriously bothered by symptoms, another 30 per cent to be moderately symptomatic, and about 25 per cent to have mild and relatively inconsequential symptoms. Around 15 per cent were found to be symptom-free. The severity and extent of symptoms were found to vary among different groups within the population.

Neither study implies that the presence of symptoms indicates a disorder. However, both suggest that, of the three groups of symptomatic persons found, the group with the largest number of symptoms would undoubtedly receive a diagnosis of mental disorder if seen by a psychiatrist, with the probability decreasing as the frequency and severity of symptoms become less.

Leighton has used the presence of symptoms not as an indicator of psychiatric disease, but rather as an index of the reciprocal of a state of health; that is, the fewer the number of symptomatic people, the healthier the population is. He then hypothesized that there is a relationship between the health of a population and the type of life in the communities in which it lives. Upon investigation of the communities his people came from, he found a number of parameters on which they could be graded, including the extent of social organization. He found that communities with a low state of organization—few and badly supported school and church groups, for example—tended to produce higher rates of symptomatic people than did communities that were well organized. This technique has also been applied by the Leighton group to an African society, the Yoruba. The findings appear to support the hypothesis.

The Leighton group is now embarking on an experiment to test whether it will be possible to change the pattern of social organization of some of the communities studied and whether, when such changes are accomplished, the rates for frequency and severity of symptoms will fall. It is clear that these studies are of critical importance to the whole structure of the theory of sociodynamics in psychiatric illness. They open the way for the testing of a great many hypotheses presently being acted on rather uncritically—such as the relationship between psychiatric illness and industrial-

ization, poverty, mobility, and education. They have not yielded significant results in previous investigations because sampling tended to be warped very strongly by differential availability of service.

Suggested Cross References

The epidemiology of psychiatric disorders is discussed in this chapter from a general perspective. For information regarding the incidence and prevalence of the various specific disorders, such as schizophrenia, mental deficiency, and psychosomatic disorders, the reader is referred to those sections in Area F which deal with the respective disorders.

computers with relevance to psychiatry are in information retrieval and dissemination, automated clinical laboratory testing, and hospital and financial record keeping.

Many of the present day applications of electronic computers to psychiatric problems are extensions of techniques developed in other fields. As their use has been made more practical and shown to be related to psychiatric practice, the applications have rapidly increased. Some of the more promising directions are listed here, but the most rewarding aspect of the use of computers in psychiatry is in the need for the scientist to modify his mode of thinking. The clinical impression is augmented by definitions of terms, by measurement, and by quantification. Processes, as well as terms, require exact definition, and computers are catalyzing a change in attitude from an impressionistic art to a quantitative science. Although little that is novel in modern psychiatry has yet been ascribed to computers, their use and the opportunities they represent herald significant changes in the clinical practice of psychiatry during the next score of years.

Description of Computers

Computers are direct descendants of rapid calculating devices, with the additional facility for sequential operations (programming) and for retention of intermediate outputs (memory), thereby extending the range of possible calculations.

Types of computers. Modern computers are electronic instruments capable of performing numerical and logical operations. These are usually classed as analog, digital, or hybrid. Analog computers utilize physical, electrical, or mechanical models corresponding to some aspect of the original object for measurement or calculation. Digital computers perform operations on numeric representations of objects. Hybrid computers perform operations in both analog and digital modes.

In the application of digital computers, the operations may be controlled by program instructions stored in the console. Programs are sequential machine instructions written in special languages detailing each logical step of the required operations. The languages vary for each machine, and among the most common are Fortran, Cobol, and Algol. The operations are carried out with speed and accuracy and without fatigue. It is the combination of memory, variety of instructions, speed, accuracy, and indefatigability that provides the basis for the many and varied applications of digital computers.

Hardware. Configurations of digital computers include a central processor, a memory, and input and output devices. The central processor is the control instrument for all operations. The memory stores both instructions and data and may be core (directly accessible to the processor for operations) or peripheral (indirectly accessible), as in magnetic tapes and random access disks.

5.2 COMPUTERS AND PSYCHIATRY

MAX FINK, M.D.

Despite the novelty, complexity, and expense of modern high speed computers, numerous applications have been developed in psychiatric research, teaching, and even clinical practice. An impetus for this interest rises from the increasing application of quantitative analytic methods in medical and biological investigations. Quantification has supplemented clinical impression and has stimulated increasing use of systematic tests of significance. The demand in computer usage for explicit instructions has forced physicians to increase the precision of their data and to prepare it in standardized, easily retrievable forms.

Applications of specific psychiatric interest are in information processing, data analysis and statistical operations, studies of language and the simulation of interviews, and model testing. General applications of

FIGURE 1. Digital computer, IBM 1800. Pictured is the central processor with control switches. In the background are two magnetic tape memory storage units. The typewriter and the card reader (to the left of the processor) are the principal input devices. In the left foreground is the high speed printer. Analog to-digital conversion is provided by the processor. (Courtesy of the I.B.M. Corporation.)

Input devices—punch card and mark-sense card readers, punch paper tape, magnetic tape, or typewriter—bring data and instructions into the processor. Output devices express the results of operations, and these may be either intermediate or final. Intermediate outputs include magnetic and punch paper tape, punch cards, disks, and digital oscilloscopes. Final output devices are printers, typewriters, plotters, and photographic cameras.

Data for digital computers may be derived from input devices located at the computer center or from devices at remote locations with communication from the input device to the processor via telephone networks. Data may also be provided from specialized input devices, such as analog-to-digital converters, optical page readers, light pens, and digital oscilloscopes. The multiplicity of input devices is increasing rapidly, and many new devices have greatly extended the range of applications to psychiatry.

Computer hardware may also be classified as to location—within a single laboratory and devoted primarily to one application or centralized for many users. Laboratory computers are frequently small, highly specialized in their input-output modes, and hybrid. Their operations are often defined by the structural configuration of the instrument. The operations are usually modified by switches and dials in the console. These computers are operated by the individual investigator with short intervals (minutes to hours)

between data collection and data processing. These include the average response computers, the LINC (Laboratory Instrument Computer), and the small, general purpose computers located within one laboratory (as in the studies of electroencephalographic (EEG) quantification using an IBM 1710-1620 system).

Centralized units are often large and varied in their peripheral components and usually operate in batch mode—that is, various programs for different investigators are serviced sequentially. In such units the time between data collection and data processing is apt to be long, perhaps days to weeks.

The varieties of equipment or hardware are great, but recent electronic developments in transistors, integrated circuits, and modular design have made the capacity and characteristics of the equipment of different manufacturers very similar.

“Software.” The great range of computer operations depends largely on the programs that are written, the “software,” rather than the type of computer. The sequential instructions that must be written accurately and in complete detail and the facility and flexibility of the machine languages are the heart of every computer operation. As almost any design or picture can be printed or reproduced on film by combining many dots of different colors, so almost any set of mathematical or logical operations can be reproduced by combinations of program instructions in a digital computer. The limits of the operations are defined by

the imagination of the scientist in picturing the problem, the ability of the programmer to translate these visions into instructions, and the capacity of the memory of the machines. It is in these instructions, the programs, that the greatest energies and bottlenecks are now found.

Applications in Psychiatry

Statistical studies. The early extensive use of electronic computers has been in statistical calculations and demographic studies. With their high speed and large memory for intermediate calculations and for complex programs, computers have made possible the general application of multivariate statistics. In demographic studies, the need for adequate definitions of illness, symptoms, and psychopathological signs has led to studies of psychiatric terms, classifications of illnesses, and an enhanced interest in symptom-rating scales. The data of population studies lend themselves to simple statistical tests.

It is in clinical trials and in the development of psychiatric typologies that the computer has had signal applications. The rapid success of clinical psychopharmacology in the treatment of psychosis stimulated interest in the early verification of clinical claims. Scientists examined the prevailing methods for therapy evaluation and found them based largely on unverified, unquantified, and uncontrolled clinical impressions. Concepts of target symptoms and psychopathological profiles were suggested to supplant general clinical descriptions. Double blind trials, placebo controls, and random assignment of populations laid the basis for more sophisticated statistical

techniques for evaluation of results and the definition of predictors. In this environment, computer techniques have been most useful in statistical *t*-tests; covariance and variance analyses; discriminant and canonical functions; and cluster, profile, and factor analyses. These techniques have been applied usefully in determination of the relative therapeutic efficacy of specified drugs for defined populations in interhospital collaborative studies; in the identification of drug-responsive and non-drug-responsive psychopathological symptoms; and in the development of rating scales with therapy-responsive items.

Other applications of these demographic and statistical approaches are seen in the classification of subpopulations of the mentally ill, in the training of staff members in identification of clinical symptoms, and in the trials of cluster analysis in the diagnosis of mental illnesses. Many studies of the diagnostic process in clinical medicine are providing the experience in programming for application to clinical psychiatry.

Information processing. The facility of electronic devices to transmit, shuffle (reorder), and retrieve information is great. With bulk storage memory devices, computers scan large amounts of data, select specific examples, process sequential operations, and transmit the results rapidly. Specific applications are found in the maintenance of patient records, documentation of interview data, demographic summaries, retrieval and selective dissemination of information, and establishment of laboratory standards.

Behavioral records. Essential to the evaluation of behavioral change in patients are descriptions by staff, family, and the patients themselves. Such descriptions are generally narrative in form and are read only with difficulty. They are frequently incomplete. Various digital applications have been developed to improve this type of data collection.

Questionnaires and rating scales are widely used. The items are scored on prepared forms, and the scores are transferred to Hollerith (key punch) cards; or the items may be printed on prepared key punched cards, and the rater simply places the individual cards into sorting bins. The clusters of cards in each bin are then scored by computer methods.

Rating scales may be completed by the examining physician, nurse, aide, or social worker; or there may be self-ratings by the patient. Many different scales have been developed, including those for the classification of the mentally ill, the evaluation of psychopathology in schizophrenia and depression, and the identification of elements of the mental status responding to treatment or useful as predictors of treatment response.

Measures of change. With many different scales as inputs, computer operations are as varied as the investigators. The items and individual scores may be sorted and listed, or the cards may be used to determine score means before and after treatment. Changes in nonhomogeneous groups may be deter-

FIGURE 3 Psychopathology rating form, prepared for optical page reading. Items are rated by the examiner for incidence (rarely, sometimes, usually, only under stress) and for severity (absent, suspicious, slight, moderate, and marked). The form is completed as used in a case of hebephrenic schizophrenia. (With permission of M. Fink, T. Ill, A. Keskiner, and D. Shapiro, University of Missouri.)

turned by covariance and variance analyses, or more complex multivariate statistics may be used to measure score changes with various treatments. Items have been studied by factor analytic and clustering techniques to determine which elements of psychopathology vary together. Populations have been identified by the similarity of their ratings, and much recent study has been devoted to identifying the subgroups of depression and of schizophrenia.

It has become possible to bypass the stage of key-

punching by the use of special rating forms that are read directly by an optical page reader and that reproduce the data in machine assimilable form (see Figure 3, for example). Such rating scales have been translated into multiple languages, and the results of the analyses have been provided in the original language of the form and in other languages for which translation programs have been written. Such instruments have recently found special utility in international collaborative evaluation studies.

In another application, an essay type of description of a patient has been produced from his responses to a self-rating inquiry form. Such machine-programmed essay reports and their questionnaires have also been translated into different formats to provide essay descriptions of the history and mental status in different languages.

Ward management. Hospital nurses' ratings, describing each patient's status each day, are completed on the ward and are immediately transferred to the computer console. Programs are of two types—comparison of the items with the patient's own record and averaging the data for the patients in one ward unit. By defining limits for changes in specified items, a computer program can rapidly determine if the subject has changed from earlier reports or, for group data, if the ward has undergone a change in scores for such items of interest as excitement, depression, or episodic impulsivity.

In another hospital application, doctors' orders, nurses' notes, measures of patient change, and laboratory data are transferred to the computer from peripheral and remote input-output units located on the wards. As the data are entered, each item is checked against established standards, providing a monitoring of doctors' orders and checking their accuracy, flagging nurses and pharmacy for the necessary supplies, scheduling treatment administration, and maintaining financial and supply records. An even more specialized use is in monitoring the physiological state of the patient and notifying the physician and the nurse when the measurements exceed predetermined limits, thus requiring immediate attention.

Information retrieval. The proliferation of large numbers of reports and studies is a special burden for the active scientist. Abstracting services have been available for decades, but only in the past few years have the storage capacity and rapid review of digital computers made large scale retrieval and dissemination systems plausible. Present information systems use documents identified by descriptors—either allotted by specialists or derived naturally by computer programs from title, abstract, and text. Retrieval follows a scientist's inquiry for those descriptors of interest to him that have been included in the memory of the system. In the dissemination problem, the scientist is notified or sent a copy of each article that comes into the system bearing descriptors included in his individual profile of interests. These systems are, unfortunately, still unsophisticated and expensive.

With the recording and storage of psychiatrically relevant data, numerous special studies have been proposed. The demographic characteristics of populations and subpopulations may be readily defined, and members of subgroups of the mentally ill can be identified for specialized studies.

As sequential clinical studies develop large banks of data for each subject, summaries of the range and variability of individual test data provide standards

specifically relevant to the subpopulations investigated. Such standards have recently been defined for the clinical laboratory test data in placebo-treated patients as comparisons for those treated with novel psychoactive drugs.

Analog signal analyses. Changes in physiological indices are important in the study of emotions and ideation. Blood pressure, heart rate, pupillary size, and the electroencephalogram are continuously changing measures. Determination of their value requires the division of the signal into discrete samples. Such conversion from a continuous analog signal to a digital value is done by direct measurement by hand or by electronic devices.

The electronic analog-to-digital converters are voltage-measuring instruments, and any signal that is naturally electrical (EEG, electrocardiogram (EKG)) or convertible to an electrical measure (galvanic skin response, heart rate) can be sampled and its value determined. The rate of sampling is selected to provide as accurate an index of the rate of change as required by the problem. The converted signals provide the basis for subsequent analyses. Computer programs have been developed for a variety of analog signals of psychiatric interest. Thus, for the EKG, programs for pattern recognition and for frequency and variability of heart rate are available. For the EEG, many measures have been programmed, including amplitude and amplitude variability, frequency and frequency variability, power spectral density and pattern (Figure 4).

The converted signals and their analyses provide numerical data that may be further analyzed by statistical methods. These measures have found special applications in psychopharmacology, where the EEG changes induced by psychoactive drugs have been related to the clinical efficacy of the compounds and to the type of behavioral response. The quantitative EEG measures have been suggested as a device for screening and classifying psychotropic drugs, for classifying psychiatric patients, and for measuring dose-response curves.

Such measures have recently had extensive application in the automatic classification of sleep stages and the determination of differences in sleep patterns in mental illnesses and in response to psychoactive drugs.

A special computer application in psychophysiology has been the averaging of cortical responses evoked by sensory stimuli. Such measures have been related to the psychological mechanisms of attention and anticipation and have been studied as a means of classifying the mentally ill.

These are specific applications to psychiatry today, and the instruments are also receiving extensive use in the analysis of models of neural functions, including the operations of nerve nets, firing patterns, and the interrelations of different cerebral structures. The simulation possibilities and large memory functions are useful in testing proposed models of cerebral ac-

FIGURE 1. Digital computer analysis of electroencephalogram. Output of base line, first derivative and amplitude analysis using period analysis program. Samples of EEG and measures during narcosis (intravenous Thiopental, 4 mg per kilogram per 2 min.). Subject was a 38 year old schizophrenic. Zero cross bands are average (AVE), variability of average (DEV), and seven frequency bands. First derivative bands are average (AVE), variability (DEV), amplitude (AMP), and seven frequency bands. AVE and DEV in cycles per second; bands in percentage of time of sample; amplitude in units relative to calibration. Sampling rate, 320 samples per second; 30-second epochs. (Courtesy of M. Fink.)

tivity and in testing neural analogs of such epistemological processes as perception, learning, calculation, and cognition. Such models of information processing are subsumed by the term "perceptrons."

Automatic personality assessment. The need for a rapid and concise personality description in clinical medicine and interest in psychological tests prompted various studies of digital computer uses. The Minnesota Multiphasic Personality Inventory was selected for study, for it is a simple, "yes-no" response inventory with extensive trial as a personality measure. Its simplicity and the availability of a set of defined rules for interpretation based on configural analysis of the responses led to the preparation of a mark-sense self-scoring form for use by patients. The programs developed included those for machine key punching and the analysis of responses, and for the production of a clinical report both as numerical scores for each scale and in a simplified narrative personality description. Similar systems for the Clyde Mood Scale and Glueck Q-Sort have also been developed.

In the analysis of other psychological tests, the problems are more formidable, since operational rules

for interpretation are not available. For example, in the Rorschach test, programs for the narrative interpretation of previously scored data have been described but are of limited application.

The "on-line" analysis of reaction time performance tasks is yet another computer application to experimental psychology. An advantage of on-line analysis is the modification in the rate or type of stimulus presented as the responses of the subject are analyzed in real time. Concurrent analysis of the EEG provides a measure of a neurophysiological response varying with the changes in performance.

Psycholinguistics. Among the numerous problems of interest to language specialists for which computer methods have been programmed are those of automatic translation, the development of dictionaries and concordances, automatic indexing and abstracting, and the rules of natural languages. These studies have engendered special programming languages that allow the manipulation of words as symbols according to rules that parallel the manipulations of alphanumeric symbols.

For the past 2 decades, the use of magnetic tape re-

orders of high fidelity has permitted the recording of psychiatric interviews for study. Some students have developed specialized instruments to study the formal aspects of dyadic interaction as the rate of speech, time of utterances, and pause length; others have depended on highly accurate transcriptions. These have been studied both for such formal aspects as variations in person and tense and for the more common interpretation of content. An interesting application has been the measurement of the dyadic type-token ratio (TTR)—an index of variability and repetitiveness in speech. The TTR has been shown to vary with mood and in response to the administration of psychoactive drugs.

Content analyses, although tedious and still highly subjective, provide a useful test of changes in therapist-patient interaction in psychotherapy. The need for validation and demonstration studies in psychotherapy is great, and much effort is expended in studies of the application of statistical methods to linguistic data.

A special application has been in the simulation of

interviews. In an elementary form, the computer asks questions, and the responses are entered into the console via a typewriter by the subject. As programs become more sophisticated, the computer's responses simulate the responses of the therapist. In addition to some practical demonstrations and their use as teaching devices, such programs are receiving intensive study to develop rules for various types of verbal interchange, including psychotherapy.

Experimental Psychopathology

5.3 EXPERIMENTAL NEUROSIS

CHARLES SHAGASS, M.D.

(Experimental psychopathology attempts to investigate abnormal behavior systematically under conditions that are more or less known or controlled. Controlling conditions may be introduced in many ways, such as manipulating the physical or psychological aspects of the environment, giving drugs, or ablating tissues by surgery. We shall here deal mainly with states produced by psychological forms of experimental manipulation.)

(Psychiatry's most urgent need is for new information about the chronic functional disorders—neuroses, personality disorders, psychoses, and psychophysiological reactions. With the possible exception of psychophysiological reactions, the symptomatic manifestations of these disorders in man are of such complexity that they cannot be reproduced in convincing detail in any other species. In studies with animal subjects, the investigator is limited to detection of behavioral changes that *appear* similar to those occurring in human disorders. His goal is to derive laws governing the animal behavior that are applicable to man in an explanatory or predictive manner. The ob-

vious advantage of animal experiments is that they can use procedures not permissible in humans. Even though experimentation in man promises a more convincing identification of the experimental and natural abnormal conditions, it is ethically restricted to induction of acute and reversible psychopathological states. Since the duration of mental disorders may be of crucial importance in determining their manifestations, the relevance of most human experiments is also open to question. Workers in the field of experimental psychopathology must accept these limitations, and those who study their findings must be aware of them.

Experimental Neuroses in Animals

Abnormal animal behavior. Criteria of abnormality may be defined in many ways, and no attempt will be made here to distinguish between neurosis and psychosis in the discussion of abnormal behavioral states in animals. Although some manifestations, waxy flexibility, for example, may appear to fall more clearly into one category than the other, there are no certain criteria for making the distinction.

From a psychiatric point of view, Hebb's approach seems highly relevant. Hebb begins by defining human neurosis in behavioral terms, without use of verbal report of the subjective state, so that the definition can be used at the animal level. He distinguishes between *neurotic behavior* and *neurosis*: the former

constitutes the signs of neurosis, the means by which it is recognized; the latter is the concept of a central state. Proceeding in this way, Hebb's definition is: "Neurosis is in practice an undesirable emotional condition which is generalized and persistent; it occurs in a minority of the population and has no origin in a gross neural lesion." (The six essential elements in this definition are as follows: (1) undesirable, evaluationally abnormal, (2) emotional, involving emotion activity, (3) generalized, implies manifestation in a number of ways, (4) persistent, chronic to some degree, (5) occurring in a minority of the population, statistically abnormal, and (6) having no origin in a gross neural lesion.)

Hebb lists three additional criteria that seem invalid to him but that have had some influence in determining what is called neurosis: (1) neurosis has no physiological basis, (2) it produces a marked change of behavior from an earlier base line, and (3) it follows some theoretically traumatic experience, such as conflict or frustration. He regards these criteria as "not essentially true." For example, to reject physiological causes of neurosis is to deny the possibility of anything but a psychological cause. It is conceivable that neurosis may be of life-long duration, thus rendering the second criterion unessential. The third is considered unessential from the fact that neurotic behavior can result from nutritional or metabolic processes.

In his paper Hebb described spontaneously occurring neuroses in two chimpanzees that appeared to meet his criteria.

Pavlov and his school. The term "experimental neurosis" was introduced by the great Russian physiologist, Pavlov, to describe abnormal behavior of a more or less chronic nature that is produced experimentally.

The best known of Pavlov's experimental neuroses occurred in a dog that had been conditioned to differentiate between a circle associated with feeding (positive stimulus for salivation) and an ellipse not associated with feeding (negative or inhibitory stimulus). The original ratio of the semi-axes of the ellipse was 2:1. Further differentiation was attempted by approximating the shape of the ellipse to that of the circle. Differentiation progressed as desired until an ellipse with 9:8 semi-axes was used. After 3 weeks of training with this ratio, the discrimination failed to improve and even became considerably worse, finally disappearing altogether.

Simultaneously, the general behavior of the animal changed abruptly. The previously quiet dog began to squeal in its stand, he kept wriggling about, with his teeth he tore off the apparatus attached to his skin, and he bit through tubes connecting his room with the observer's room. This behavior had never previously occurred. Also new was the violent barking of the dog on being taken into the experimental room. Pavlov interpreted the behavioral changes as symptoms of acute neurosis.

Pavlov formulated three possible causes for experimental neurosis. (1) Excessive stimulation of inhibitory processes. This occurred in the experiment just described. (2) Overstrain of the excitatory process by extraordinarily strong or unusual stimuli. This is illustrated by the natural experiment occasioned by the Leningrad flood of 1924. All the animals had to swim for their lives through a storm. All their conditioned reflexes disappeared, and one of them developed a chronic neurotic condition. (3) Conflict between cortical inhibitory and excitatory processes. This mechanism is described in a dog that was able to discriminate between a positive tactile stimulus at the rate of 24 a minute and a negative one at the rate of 12 a minute. When one type of stimulus followed the other without a pause, the animal developed signs of a neurosis that lasted several weeks.

Pavlov's recognition of the potential significance of these observations for understanding abnormal human behavior was to have a profound influence on the focus of investigation in his own laboratory and in conditioning laboratories elsewhere. However, Broadhurst, who recently attempted to evaluate the Russian research in the light of Hebb's criteria, was forced to conclude that the Russian findings provided insufficient information about the responses of the animal outside the experimental chamber. Because of this, the results on experimental neurosis originating in Pavlov's laboratory do not convincingly meet Hebb's criterion of generalization of the abnormal behavior. It is also not clear that the behavior was statistically abnormal.

Gantt and his school. The Pavlovian laboratory at The Johns Hopkins Medical School, directed by W. Horsley Gantt, has been a principal American contributor to the study of experimental neurosis. An outstanding feature of the work is the provision of detailed case histories.

Case history of Nick. One mongrel dog, Nick, was studied for 12 years. In 1932 he was about 3 years old, active and playful. He appeared normal then but was more restless than most dogs during adaptation to feeding in the experimental room and slow in showing conditioned salivary response. When auditory differentiation was introduced (learning to respond to one tone and not to another), he refused food and showed a defense reaction. A rest restored food acceptance, but, with an increase in difficulty of the discrimination, he again refused food and continued to do so in the laboratory for most of his life.

In the following year, all conditioned responses failed, and Nick ate more readily the farther he was away from the experimental room. In the room he showed a stereotyped restlessness whenever he was released from the apparatus. He rushed about, jumped up on the table and off it again, fumbled the uneaten food in his mouth and dropped it.

As time went on, fresh abnormalities were observed. Disturbed respiration took the form of loud, forced

breathing whenever he was excited, especially when approaching the experimental room or people connected with the experiment. Gantt repeatedly noted that Nick was friendlier toward strangers than toward anyone associated with the experiment.

From the end of 1936, Nick began urinating when brought to the experimental room, with a frequency as high as 25 times in 30 minutes. This could not be inhibited by punishment. Concurrently, abnormal sexual excitation, as judged by penile erection, was observed during conditioning stimulation. These persistent sexual erections contrasted with the occasional short erections normally seen in young male dogs. It is noteworthy that both the urinary and sexual abnormalities occurred after a bitch in estrus had been used in the experimental situation in order to test the effect of normal sexual excitation on Nick's other abnormal signs.

Gantt observed wide generalization outside the experimental situation. He kept Nick on his farm in the country and found that the particular food given as reinforcement in the experimental situation was consistently refused there and that the signs of sexual erection, frequent urination, disturbed respiration, and a marked increase in heart rate were sometimes observed when people associated with the experiment, or even members of their families, approached the animal.

In relation to Hebb's criteria, Nick's behavior was frequently undesirable, for example, his refusal of food when hungry. It was markedly emotional, judging by overt signs. An autopsy report showed that he had no gross neural lesions. The persistence of the behavior pattern was strikingly well established, as was the generalization of the behavior to situations other than the experimental. The question of statistical abnormality is difficult to assess.

Schizokinesis and autokinesis. Gantt has introduced two fundamental theoretical concepts: schizokinesis and autokinesis.

Schizokinesis implies a cleavage in response between the emotional and visceral systems and the skeletal musculature. The concept originated in observations suggesting that cardiac conditioned responses are formed more quickly than motor responses, are of comparatively greater intensity, and are more resistant to extinction. Gantt considers schizokinesis to be a built-in unacquired mechanism, the function of the normal organism.

Autokinesis refers to the internal development of responses on the basis of old excitations. This is seen in the spontaneous restoration of extinguished conditioned responses and the appearance of signs of experimental neurosis long after the causal conflict has been removed. For example, new symptoms arose in Nick months or years after he was removed from the stressful laboratory environment. Moreover, although occurring much later than the original stress, the new symptoms were related to that stress, as could be seen

by their ready evocation by the original environment or its elements. Gantt also distinguishes between negative and positive autokinesis. The development of new symptoms in a neurotic animal is negative, whereas improvement occurring some time after a specific therapeutic procedure such as a drug has been administered may be considered positive.

These concepts are primarily descriptive and rather broad; however, they draw attention to phenomena that may be of considerable importance to psychopathology.

Liddell and the Cornell group. The Cornell University group, led by H. S. Liddell, succeeded in producing chronic abnormal states in several animal species, using conditioned reflex techniques. Single animals were observed for as long as 12 years.

Anderson and Parmenter described three types of procedure: (1) difficult differentiations, (2) experimental distinctions, and (3) rigid time schedules. The first procedure is similar to that used by Pavlov in the circle-ellipse differentiation. The second consists of following the positive (food) stimulus with an exceedingly long series of negative (no food) stimuli. The third involves the use of a monotonous, lengthy routine of alternating positive and negative stimuli.

Manifestations of experimental neurosis. The many manifestations of experimental neurosis included hyperirritability, tenseness, and restlessness during the experiment; inhibitory motor reactions; change in diurnal activity cycle; respiratory and cardiac changes; recorded in the barn as well as in the laboratory; changes in micturition and defecation patterns in the laboratory; social and emotional changes.

(Some of these are of particular interest. The inhibitory motor reaction in some animals involved rigidity of limbs; they could be placed in various abnormal positions, reminiscent of catatonia with waxy flexibility. Motor activity was measured by a pedometer; the daily total in neurotic animals was not significantly different from normal animals, but neurotic animals showed about as much activity during the night as during the day, whereas normal animals showed little or no activity during the night. This seems parallel to insomnia in man.)

(With respect to social behavior, neurotic dogs and sheep exhibited shyness, tending to remain alone and lacking normal gregariousness. They went hungry when it was necessary for them to get their food from a common source. When cornered, the shy, neurotic animals became aggressive and would bite, struggle, or kick.) Neurotic sheep and goats also appeared handicapped in their ability to cope with real danger. On several occasions, dogs invaded the pasture, and each time their victim was invariably one of the neurotic animals.

Causes of abnormal behavior. Liddell did not agree with Pavlov's hypothesis that the cause of the abnormal behavior is a clash between intense cortical excitations and inhibitions. He assigned considerable

importance to the factor of restraint, introduced by negative conditioned stimuli, and showed that animals allowed to run at will in a maze while attempting to solve extremely difficult problems never developed disturbances. He thought the experimental neurosis was caused by the equivalent of a human conflict situation. The animal must decide whether or not to respond, and if the decision is too difficult, there is a drastic change in nervous system functioning, resulting in signs of neurosis. Other workers also found that restraint facilitated neurotic disturbances in the pig, cat, and rat.

Liddell also emphasized the importance of vigilance in experimental neurosis. The trained sheep or goat had initially struggled to escape from its restraining harness but had learned to restrict its movements to a precise limited response of the foreleg to electric shock. Its autonomic functioning, however, suggested a strong emotional undertow. On one occasion, a trained sheep was placed in the harness with electrodes attached to the foreleg and kept there for the customary hour without being given the usual signals or shocks. By the end of the hour, its breathing had become labored, and the respiratory rate had risen from 41 to 135 a minute.

Observations such as these forced Liddell to conclude that the conditioned reflex described by Pavlov was not an example of ordinary learning. He saw it as an emotionally charged episode of behavior bracketed between two primitive stereotyped reactions, the vigilance reaction and the unconditioned reaction to the reinforcement of the conditioned stimulus by food, electric shock, etc. He equated the conditioned reflex with the emergency reaction in response to danger, interpreting the waiting for the stimulus as a persisting apprehensive watchfulness in the animal.

Relation to criteria of abnormality. How well do the results obtained by Liddell's group meet Hebb's criteria of abnormality? It seems clear that many examples of behavior were undesirable, emotional, and persistent, and there is no evidence that they may be attributed to a gross neural lesion. However, the criterion of generalization from the laboratory to other situations is not so easily met. The fact that change in pulse and respiratory rates could be recorded from the barn can be interpreted as a conditioned response to the apparatus used for measurement. The apparently decreased capacity to cope with actual danger seems more convincing, but the finding is derived from incidental and uncontrolled observation. The issue of statistical abnormality is also difficult to decide; apparently about 25 per cent of the animals developed experimental neuroses. The Cornell animal data thus approach, but do not fully satisfy Hebb's criteria.

Masserman's experiments. Masserman's biodynamic approach is associated with a long series of experiments in which experimental behavior disturbances were produced in conditioning situations. The basic experiment requires learning to open a food box

in response to a sensory signal. Various complexities were introduced into the experiments; for example, to obtain food, animals learned to press a series of switches a definite number of times in a required order or to differentiate between printed signs. The usual technique of inducing neurotic behavior in cats, dogs, or monkeys was to present a traumatically deterrent stimulus during the execution of the well learned response. Stimuli were electric shock, a startling air blast across the food box, or, even more effective in the case of monkeys, the sudden appearance of the head of a toy snake when the food reward was about to be taken. If the traumatic stimulus was repeated several times (two to seven in cats or dogs, generally more in monkeys), behavioral aberrations appeared.

Some of the symptoms of disturbance may be described under the interpretive headings used by Masserman.

Pervasive anxiety was indicated by low threshold of startle, persistent hyperirritability, muscular tension, body postures, mydriasis, irregularly accelerated pulse rate, raised blood pressure, and increased coagulability of the blood.

Psychosomatic symptomatology included, in some animals, recurrent asthmatic breathing, genitourinary dysfunction, anorexia, flatulence, and diarrhea.

Defensive reactions included inhibition of feeding, even outside the experimental apparatus, to the point of self-starvation and serious cachexia.

Phobic aversions were observed, first to stimuli directly associated with the traumatic experiences, then spreading to other situations.

Sexual deviations included diminished heterosexual interests and accentuated homosexual activity.

Sensorial disturbances were considered present on the basis of behavior ranging from extreme sensitivity to minor changes in the surroundings to recurrent episodes of apparent disorientation and confusion. Hallucinations were thought to be present in monkeys who, although refusing food readily available in their food-box, could be observed picking up nonexistent pellets and appearing to chew and swallow these.

Masserman was particularly interested in procedures for ameliorating the manifestations of the disturbances induced in his animals. He found a number effective to some degree. They ranged from petting by the experimenter to neurosurgical operations.

From the point of view of Hebb's criteria, the behavioral disturbances produced by Masserman do not easily qualify as neuroses. The behavior was not statistically abnormal, and neither its persistence nor its generalization was satisfactorily demonstrated. With respect to the animal's adjustment, it is also not clear that the behavior was abnormal.

Conditioned emotional response versus specific state. It has been suggested that experiments of the Masserman type, involving inhibition of feeding responses by the introduction of fear-arousing stimuli, should be regarded as eliciting conditioned emotional

responses. Such responses carry no implication of a specific abnormal state. Masserman has argued against this interpretation, contending that the generalization of anxiety reactions to many other situations only remotely or symbolically associated with the original one is characteristic of *human* neurosis and not of a simple conditioned response.

The crucial issue appears to be whether the experimental neurosis can be understood in terms of general laws of learning or whether it represents a specific state requiring special conditions, such as conflict and restraint, for its production and implying some form of constitutional susceptibility to breakdown. The view that experimental neurosis is learned behavior is favored by Wolpe and is supported by the results of his experiments. These were carried out on cats in a situation like that used by Masserman but were distinguished by use of a control group, which received no initial training to feed on hearing a signal. Nevertheless, electric shock produced behavioral disturbances in all animals. These disturbances could be ameliorated by placing the hungry animal in a room enough unlike the experimental room to allow feeding and then gradually making the feeding environment more like the experimental room. Wolpe's animal studies led him to work out related procedures for treatment of human neuroses.

One striking difference between the results of Pavlov, Gantt, and Liddell on one hand and Masserman and Wolpe on the other is that all animals were made neurotic by the latter workers and only some by the former. If one scrutinizes the experimental situations for a reason, the clearly traumatic stimuli used in the Masserman procedure present an obvious difference. Pavlov and Liddell had to postulate that the apparently innocuous demands of their experimental situation for perceptual discrimination or delay of response generated conflict and strained the capacity of the nervous system. Masserman's and Wolpe's animals fed normally until exposed to stimuli universally disturbing to that species. It would appear that the need for inhibition or restraint brings out much greater individual differences in susceptibility of animals to experimental neurosis than does exposure to traumatic stimuli. One may speculate about possible parallel differences between the spontaneous neuroses of human civilian life and those that occur under war combat conditions.

Personality types. If susceptibility to experimental neurosis could be shown to depend upon constitutional factors, this would reinforce the hypothesis that they reflect a specific central state. In his writings, Pavlov paid considerable attention to possible constitutional differences between dogs. He applied the humoral classification of Hippocrates to his experimental animals, describing them as sanguine, phlegmatic, choleric, and melancholic. He noted the appearance of neurotic behavior only in dogs of the melancholic

type—timid and docile with predominance of inhibitory process—or of the choleric type—aggressive and excitable with excitatory predominance. Initially well balanced animals (the phlegmatic or sanguine types) did not develop chronic disturbances in behavior. The specific state issue might be resolved if other workers could confirm these observations with more exact methods of characterizing animal personality.

Pavlov did discover a pharmacological correlate of his neurotic types. He found that temporary administration of bromides resulted in apparently permanent improvement of dogs with neuroses of the excitatory type. Treatment of the inhibitory type of neuroses was unsuccessful until he used a very small dose, only a fraction of that beneficial to the excitatory type. These observations indicate that the manifestations of a disorder are related to drug reactivity, and they favor Pavlov's theory of types, since it is easy to consider drug reactivity as an aspect of constitutional makeup. Of further interest is the fact that there are some consistent parallels between Pavlov's findings on reactivity to bromide in neurotic dogs and reactivity to amobarbital in psychiatric patients, as has been shown by Shagass.

Psychosomatic Disorders in Animals

Throughout the experimental neuroses tests, various physiological disturbances were frequent accompaniments of the behavioral manifestations. Often they were the most convincing signs of disturbance, as in the case of Liddell's sheep, whose respiratory rate rose to 135 a minute. It seems clear the psychophysiological reactions form an integral part of the picture of experimental neurosis. One could also argue that the experimental neurosis is a psychophysiological reaction, since the experimental methods are essentially similar.

Gastrointestinal disorders. There has been considerable work on experimental induction of functional and structural changes in the stomach. Mahl carried out a series of studies on the effects of chronic fear in dogs and monkeys and added some observations in man.

Dogs were stimulated under control conditions day and night by a 20-second buzzer that occurred unpredictably at intervals of 5, 10, or 15 minutes. In the chronic fear condition, the buzzer stimulation continued, and some buzzers were accompanied by a brief but painful electric shock, delivered to the animals through the grid floor of the cages. The animals developed conditioned fear to the buzzer and the cage; this was manifested by motor withdrawal activity, paralysis, trembling, widespread autonomic changes, and intense vocalization. Measurements of free hydrochloric acid (HCl) and total acidity showed significant increases in both. The dogs were then allowed a recovery period, being removed to different cages in a rest room, with no buzzer or shock stimuli. Later

they were returned to the experimental cages and were stimulated for 5 hours with only the buzzer. During this conditioned fear phase, there was an increase in gastric acidity. Results were similar in monkeys.

Mahl concluded that sustained fear is accompanied by increased HCl secretion in dogs, monkeys, and humans and that conditioned fear stimuli evoked increased HCl secretion in the absence of pain stimulation. By contrast, HCl secretion is inhibited during episodic fear stimulation. Mahl found no evidence of stomach lesions in his animals.

Other investigators have been able to produce lesions and to study the relevant conditions. Weisz divided 90 rats into six split litter groups of equal size and placed each of these in a different experimental situation. Two situations involved an approach-avoidance type of conflict; two were fear-producing, with food and water deprivation present in one but not in the other; two were control situations, involving only food and water deprivation or food and water deprivation plus the facility to see and smell food and water. Significantly more animals in the two conflict situations and in one fear-producing situation developed ulcers in the rumen of the stomach than the comparable animals in control situations.

The data suggested that severe food and water deprivation was a necessary prerequisite for the occurrence of the stomach lesions, although not sufficient in itself. Thus, this experiment showed that both conflict and chronic fear result in gastric lesions. Prolonged immobilization will also produce gastric erosions in the rat, as shown in the experiments of Ader et al. The postulated chain of events is that these various stresses cause prolonged gastric hypersecretion, with increased acidity, resulting in an excessive volume of unbuffered gastric juice coming into contact with the upper portion of the stomach, which is not as well protected by mucosa as the remainder.

Porter et al. have demonstrated that experimental psychological stress may produce gastrointestinal lesions in the monkey. In 11 of 19 animals subjected to conditioning programs directed toward a study of emotional behavior, there were lesions, which included gastric hemorrhage and erosion, duodenal ulceration, enteric intussusception, and chronic colitis. The conditioning programs differed for each animal, so comparisons for the group as a whole were not possible.

However, in two pairs of monkeys a controlled study was carried out on avoidance behavior. Two monkeys were strapped to a restraining chair, and one member of each pair was reinforced in such a way that an avoidance response was developed, while the other member of the pair received just as many shocks but no specific reinforcement. The member of each pair learning the avoidance response died first and showed duodenal ulceration at autopsy; the control animals, which were killed at the same time, showed no abnormality. French et al. produced similar lesions by

electric stimulation to the hypothalamic region over a prolonged period of time; this suggests that the avoidance conditioning situation may involve chronic high level excitation of the visceral brain stem.

Asthma. It is possible to induce asthma experimentally in the guinea pig by sensitizing the animal to egg white; asthmatic attacks will then occur in response to a spray of homologous antigen. The reactivity to antigen varies, but Ottenberg et al. found that consistently reactive guinea pigs displayed attacks when placed in the experimental chamber in the absence of the egg white spray. The asthmatic attacks of these animals appeared to be a conditioned response to the chamber.

The respiratory pattern associated with pain-fear response to electric shock resembles that found in experimental allergic asthma but actually involves different mechanisms. Schiavi et al. determined this by measuring several respiratory characteristics and the mechanical properties of the lungs. Under both conditions, inspiration was shortened, and expiration was prolonged. However, there was evidence of bronchiolar obstruction in experimental allergic asthma, whereas no increased airway resistance was found in the animals exposed to electric shock. This study provides an excellent example of the fact that detailed measurement and analysis of physiological functions can demonstrate that different mechanisms can be involved in an apparently similar bodily reaction pattern.

Various other physiological reactions that may be taken as representative of psychosomatic disorders have been studied in animals. The examples cited here are among the most sophisticated and give some idea of the methods and problems.

Studies of Neuroses in Man

A number of experimental strategies have been used to obtain observations relevant to the problems of neurosis and psychophysiological dysfunction in man. One obvious approach is to compare individuals who clearly suffer from the condition under examination with controls not so afflicted. However, although functional difference between sickness and health may be ascertained by this approach, the findings leave uncertain the antecedents of illness. For example, to show that neurotic patients have higher heart rates than healthy controls does not reveal much about the genesis of neurosis, although it may help clarify a symptom mechanism. Another approach is to attempt to reproduce the manifestations of illness in healthy subjects in a temporary and fully reversible fashion. Techniques such as hypnotic induction of conflict and emotion and the application of controlled stressful stimuli have been used for this purpose. Conditioning techniques have also been applied. In addition, a number of investigators have availed themselves of naturally occurring stress or conflict situations, such as the time preceding college final examinations, to

make observations of temporary disturbances in ordinarily healthy subjects.

Hypnotically induced conflicts and emotions. Prior to considering the use of hypnosis in various experimental procedures, attention should be drawn to the fact that the status of the hypnotic trance as a special state is currently under active investigation and remains uncertain. The major difficulty arises from the fact that virtually all objectively observable changes that may be recorded during the trance state may also be elicited by verbal instructions or suggestions in un hypnotized subjects. However, the controversial and uncertain status of hypnosis need not prevent us from accepting the results of experiments using hypnotic methods if these methods are regarded merely as effective ways of instructing the subject.

Luria method. The Russian psychologist Luria employed hypnotic induction, together with a special method of recording motor effects, for the study of human conflicts. In a typical experiment, a story was told to the hypnotized subject; according to the story, he had committed a reproachable act, one that was contrary to his usual personality trend. A number of critical words were taken from this story and placed in a list of control words not specifically related to the story. The list was then presented as an association experiment. With each verbal response, the subject was required to press on a tambour with his preferred hand. Control sessions were carried out before and after the hypnotic experiment in which the conflict was induced and later removed. In addition to the voluntary pressure curves, verbal reaction time to the words and, in some cases, involuntary movements from the nonpreferred hand and respiration were recorded. The signs of conflict consisted of irregular hand pressures, lengthened reaction times, and, when recorded, irregular respiration.

Luria derived several laws from his numerous experiments. He used concepts reminiscent of Pavlov. For example, in his "law of the decreased action of the functional barrier," the functional barrier (a cortical property involving regulation of motor activities by inhibition) was weakened by excessive emotional excitation.

Huston et al. repeated one of Luria's experiments. They used hypnosis to induce a conflict in 12 normal subjects. The story used for this purpose in one subject follows. The young man met an attractive girl who was wearing a new, brown silk dress that was very important to her. He accidentally burned a cigarette hole in her dress and allowed her to believe that she had done it herself. Words such as silk, dress, brown, cigarette, burn, and hole were selected as critical and placed in a long list of noncritical words. Apart from test responses, there appeared to be good evidence that strong emotional conflict was produced by the procedure. The conflict was not removed in this subject for 24 hours after the hypnotic session. That night he slept poorly, awakened with a headache that

persisted until the removal of the conflicts in the afternoon, had poor appetite, was resentful and antagonistic toward the hypnotist, and was somewhat uncooperative. He was unable to give any reason for these manifestations. Throughout the day he gave away his cigarettes and apparently could not enjoy smoking. He rationalized this behavior by saying that he was giving up the habit.

In the group of 12 subjects, 9 appeared to accept the story told to them as something they had done, and it produced a profound reaction in them. In 6 of these 9 subjects, some motor aspect of the Luria technique revealed the presence of the conflict in either the hypnotic or waking states. In the hypnotic state, they tended to give verbal responses definitely related to conflict, with few nonverbal disturbances; the reverse was found in the waking state, in which there was a relative increase of nonverbal disturbances over the verbal. This suggests that if the excitation created by the conflict is not discharged verbally, there is a spread to the voluntary and involuntary motor levels.

Wittkower's experiments. The wide range of bodily functions that may be altered when hypnosis is used to produce emotional reactions is well illustrated in the monumental report by Wittkower. He was able to produce x-ray evidence of fluctuations in the size of the heart, with both enlargement and diminution of heart shadow occurring in different subjects. Salivary secretions were altered both in quantity and in chemical constitution. Gastric motility and acidity were either increased or decreased; the nature of the gastric reaction was characteristic for the individual, even with different emotions, but differed from one subject to another. Wittkower demonstrated changes in the amount of bile and the chemical constitution of bile, alterations of leukocyte counts, and changes in the serum calcium, potassium, and chloride content. He also observed changes in the urine, in the blood iodine content, and in the galvanic skin response (GSR). Wittkower's main purpose was to demonstrate the profound bodily effects of psychological states. He drew attention to the need for integrating observations of multiple reaction systems if one is to understand the total emotional reaction. Although he considered his findings to be in accord with Cannon's emergency theory, he felt that it was necessary to go beyond it and to pay attention to constitutional and experimental factors that could influence the direction and quality of the organ reaction.

The basic technique used by Wittkower has been employed in a large number of experiments with various types of physiological recording. A recent example is a study of respiratory responses by Dudley et al., which showed that increased ventilation and oxygen consumption followed meaningful hypnotic suggestions of situations eliciting anxiety, anger, exercise, and head pain. Anger, anxiety, and exercise, all of which involve an orientation toward action, were contrasted with depression, the suggestion of which resulted in no

respiratory changes. Depression does not involve an action orientation. These results with respiration seem to parallel those obtained by Kehoe et al. in relation to secretion of gastric acid; the highest gastric secretory rate was associated with suggested anger and the lowest with helplessness-hopelessness. There is also some similarity to the findings with plasma hydrocortisone level, which Persky has shown to be increased by hypnotically induced anxiety.

Specificity of attitudes in psychosomatic disease.

Hypnotic techniques have also been used to provide evidence bearing on the specificity of attitude hypothesis in psychosomatic disease, which was proposed by Grace and Graham. The hypothesis states that each attitude toward a disturbing situation is associated with its own specific disease or set of physiological changes. In one study, Graham et al. hypnotized normal subjects, who were told to assume attitudes that the original study had found to be associated with hives and Raynaud's disease. With the hives attitude, the person sees himself as being mistreated and receiving injury, without developing even a wish to take any action himself. With the Raynaud's attitude, on the other hand, the person wishes to take some direct hostile action. Warming of the skin is part of the physiology of hives, whereas cooling is characteristic of Raynaud's disease. Skin temperatures, recorded during hypnotically induced attitudes, showed an average tendency for increase with the hives attitude and a tendency for decrease with the Raynaud's attitude. The results were taken to support the specificity of attitude hypothesis. Recent evidence indicates that similar effects can be obtained without hypnosis.

Conditioning. Application of the method of conditioning to studies of children began in 1907. In 1925, Krasnogorski reported observations in children that seemed to be analogous to the experimental neurosis in dogs. In one child, under conditions requiring a difficult discrimination between different rates of a metronome, latent periods of the positive conditioned reflexes first increased in length. At the same time, the child, who had always been easy to deal with and quiet during the experiments, became irritable and refused to go to the laboratory. The ward reported that his behavior had changed, that he had become rude, fought with other children, insisted upon being discharged, and was disobedient. In the laboratory, previously accomplished differentiations were then lost, the negative stimulus was associated with yawning and sleepiness, and the child went to sleep for the first time in a period of 5 months of conditioning study. This child, presumably behaviorally healthy when the experiments began, thus became emotionally disturbed.

One may, of course, criticize interpretation of this reaction as experimental neurosis. It may be normal for a child required to undergo repeated exposure to a difficult laboratory situation to become upset. Furthermore, the generalization to the ward situation could

have been determined mainly by anticipation of further exposure to the unpleasant laboratory situation.

More recent research in the Soviet Union, notably that of Bykov, has provided experimental demonstrations that a large number of bodily functions obey Pavlovian laws of conditioning. These experiments provide a basis for relating visceral dysfunctions to symbolic cues that have acquired meaning on the basis of previous experience. Furthermore, Razran's experiments on semantic conditioning indicate that bodily reactions may be elicited in response to verbal cues that are different in form from the initial stimuli but that have a similar meaning or a strong, previously formed, associational bond.

For example, after establishing conditioned salivation to the word "black," just as much response will be obtained from its antonym, "white," whereas another color name that has low associational relationship, such as "ochre," elicits much less response. Psychotherapeutic exploration is often concerned with working out specific examples of this phenomenon, for example, when the patient reports an attack of dyspnea under particular circumstances that have only an associational relationship to symbols of previous conflict or trauma.

Mention should be made of the recent upsurge of interest in the application of conditioning techniques to comparative study of psychiatric patients and normal subjects. A detailed account of the various differences found between particular kinds of psychiatric patients and normal subjects is beyond our scope, but several books, of which Ban's is an example, have appeared recently.

Experimental stress. The idea that disturbed behavior and bodily reactions occur in response to severely taxing environmental conditions is in accord with general human experience and is widely accepted. Since environmental demands or stimuli that place strain on reserve capacities of the organism are relatively easy to produce in the laboratory, much experimental work has employed this method. Unfortunately, investigators have used the word "stress" to characterize a wide variety of experimental demands, from performing mental arithmetic tasks to exposure to severe temperature conditions or physical injury. Such indiscriminate use tends to deprive the term of its meaning.

Partial starvation. Among the most biologically meaningful procedures for studying stress are those that involve complete or partial frustration of basic organismic needs for food, sleep, or environmental stimulation. The effects of sensory and sleep deprivation are given special consideration in other sections of this textbook.

Partial starvation over a prolonged period of time may result in various psychoneurotic manifestations. The most systematic data come from the Minnesota studies conducted by Keys et al. Thirty-six apparently normal young men, after 3 months of control on

a good diet, were subjected to 6 months of semistarvation, with provision of only half of their required caloric intake. Although tests of intellectual functioning and the Rorschach projective test demonstrated no significant changes, the subjects became depressed, moody, and apathetic, felt that they were not alert mentally, and reported that they had lost ambition. The scores on the Minnesota Multiphasic Personality Inventory were in accord with these reports.

Nine of the subjects were thought to develop specific neurotic behavior and ideas. Four of these showed character disturbances, with inability to maintain their former standards of morals and honesty. One man had sensory and motor disturbances of hysterical character. One man mutilated himself twice. Bizarre behavior in connection with food was almost universal and often took the form of compulsive rituals. The subjects reported irritability and anger, which they were unable to express because of the effort involved. The disturbances were reversible with restoration of an adequate diet.

Brief laboratory stresses. The more commonly employed laboratory stress procedures are probably less biologically significant because of their brief duration. Variants of pain stimulation have been employed in several ways. Pain has proven particularly useful as a standardized stimulus to elicit differential physiological reactions in different types of psychiatric patients and healthy subjects.

In general, it appears that individuals with already established illness or proneness to anxiety tend to react to moderate pain stimulation with greater physiological disturbance in various organ systems than individuals who are free of illness. Similar differentiations may be obtained by nonpainful stresses, such as those requiring the execution of difficult tasks. Furthermore, it has been demonstrated that the physiological system that is particularly responsive to experimental stress is more likely to be one habitually involved in the patient's illness, that is, one that produces symptoms. For example, headaches frequently result from sustained contraction of head and neck muscles, whereas symptoms such as palpitations, dyspnea, and precordial pain involve altered functioning of the cardiorespiratory system. By subdividing psychiatric patients, according to their complaint history, into head and heart complaint groups and subjecting them to a standard pain-stress test, it was possible to show significant differences in the affected response systems. Increased neck muscle contractions were more often elicited in head complaint group, and changes in pulse rate and respiration were more often found in the heart complaint group, even though very few of the subjects reported actual symptoms during the stress procedure. Interesting as they are, findings such as these leave unanswered the important questions concerning the events leading to symptom choice, that is, the reason for localization of dysfunction in particular organ systems.

A laboratory stress technique that has been gaining increasing favor involves the use of motion picture films, selected as being likely to induce particular kinds of emotional reactions. For example, Lazarus et al. showed subjects films of puberty rites in primitive tribes, involving incisions made in the genital area, and recorded their physiologic reactions. The powerful effects of the films were reflected in the recordings. The investigators were able to relate the nature of the reactions to some personality variables and to the kind of psychological mechanisms employed to deal with emotionally disturbing stimuli.

A further technique has been the deliberate manipulation of events in a laboratory situation in order to arouse emotions the investigator wanted to study. For example, Funkenstein et al. deliberately created a situation in which the subject was required to carry out computational problems at a very rapid rate while the experimenter became critical and demanding. The subject's behavioral reaction to this was classified as reflecting either "anger in," "anger out," or anxiety. Significant differences in various cardiovascular measures were found between the "anger in" and "anger out" groups.

Probing interviews. Interviews that deliberately focus on emotionally charged material so that related bodily reactions may be studied represent another variant of experimental stress. This is generally not standard, although it can be made so. After a baseline interval, the topics considered emotionally relevant are introduced, and discussion centers about these. Usually there is a phase of reassurance following the emotional arousal. At times the material may be introduced after the subject has been hypnotized. Behavioral observations and physiologic recordings are made, and the various responses are correlated with the ongoing stimuli. Although this procedure involves numerous methodological difficulties, it has yielded valuable data concerning the participation of physiological response systems in symptom mechanisms.

Current perspective. It will be apparent to the reader that psychiatry still lacks truly satisfactory experimental techniques for study of neurotic and psychosomatic disorders. However, the available methods do permit some insights concerning relevant mechanisms, and their use has been associated in recent years with a rather remarkable development of objective techniques for measuring numerous kinds of responses. Thus, although we are constantly working with data of limited significance, these are becoming more reliable and will provide a firm basis for future synthesis.

Suggested Cross References

Neurotic disorders are described more fully in Area F, which deals with the psychiatric syndromes. In that same area, there are chapters on psychosomatic medicine, where that topic is discussed in greater detail.

For more material on hypnosis, see Spiegel's section (Section 34.4) in Area G, on psychiatric treatment.

5.4 HALLUCINOGENS

ARNOLD J. MANDELL, M.D.

LOUIS JOLYON WEST, M.D.

Hallucinogens can be defined as substances that, administered in pharmacological doses (not toxic overdoses), create gross distortions in perception without significantly obtunding consciousness. These distortions frequently include hallucinations. Such compounds usually exert profound effects on mood, thought, and behavior. Such effects resemble the disturbances seen in naturally occurring psychoses. Thus, some hallucinogens have been termed "psychotomimetic" or "psychogenic" drugs.

The psychological changes effected by these chemicals have sometimes been described as a "loosening of ego structure," "dissolving of ego boundaries," or "disrupting of ego defenses." Such changes may include the experiencing of thoughts, feelings, and perceptions that are usually outside the individual's awareness ("unconscious" or "repressed"). Persons undergoing a psychedelic experience have also been described as being unusually suggestible, emotionally labile, and unusually aware of their own reactions and the reactions of others. Feelings of transcendence of ordinary experience and distortions in time perception have also been reported.

Hallucinogenic agents have been of growing interest to psychiatrists during recent years for several reasons: (1) Some scientists and clinicians have deliberately taken these compounds to produce psychotic-like symptoms as a means of enabling themselves to empathize better with severely ill psychiatric patients. (2) In experimental psychopathology it has been hoped that the study of chemically induced model

psychoses would lead to a better understanding of those found in clinical practice. (3) Certain therapists have defined psychotogens as psychedelic or mind-realizing substances, useful to expand perceptual and experiential horizons in the treatment of a variety of patients with alcoholism, rigid personality patterns, frigidity, etc.

An increasing number of people are taking various psychotogenic substances (marihuana, lysergic acid diethylamide (LSD), psilocybin, dimethyltryptamine), frequently acquired through illegal channels and employed without medical supervision, in order to participate in special group experiences having cultlike characteristics.

Occasionally, persistent psychotic reactions and prolonged delirious reactions have followed the administration of these substances, and psychiatrists have then been called on for help.

Pharmacology

There are four major chemical classes of hallucinogens: the indole alkaloid derivatives, the piperidine derivatives, the phenylethylenamines, and the cannabinoids.

Indole alkaloids

Tryptamine derivatives. The simplest of these substances is tryptamine, which has no hallucinogenic effect. Its *N,N*-disubstituted derivatives, perhaps having easier access to the brain, comprise several active members of the series.

N,N-Dimethyltryptamine is found, together with bufotenine, in the Caribbean cahobe bean, chewed by certain natives to produce religious visions, and in the

seeds of the domestic morning glory plant, used for hallucinatory experiences in the United States.

Various homologues have been synthesized, including *N,N*-diethyl-; *N,N*-dipropyl-; and *N,N*-diallyl tryptamine.

The *hydroxylated N,N*-dimethyltryptamines are also active. Among these are the 4-hydroxy (psilocin) and its phosphorylated derivative (psilocybin, found in the ritually employed hallucinogenic mushroom *Psilocybe mexicana* of southern Mexico); the 5-hydroxy (bufotenine, originally isolated from the skin of toads) and its more active 5-methoxy derivative; and the 6-hydroxy-*N,N*-dimethyltryptamine.

Dimethyltryptamine is psychotogenic at 1 mg. per kilogram levels (administered intramuscularly); effective dosages of the others vary. Psilocybin and psilocin produce effects at 4 to 8 mg. in man. A recent addition to the tryptamine family is α -methyltryptamine, which has been shown to be effective at a dosage level of 20 mg. in man.

Harmine, harmaline, and ibogaine. A drug with a three-ring aromatic system (harmine) and its related dihydro derivative (harmaline) are isolated from shrubs and used by South American Indians to produce hallucinatory states. The indole alkaloids with a larger ring structure include ibogaine, used by African natives to remain motionless for as long as 2 days while stalking, but producing confusion, drunkenness, and hallucinations if taken in large doses.

Lysergic acid diethylamide (LSD). The ergot alkaloids were originally isolated from a grass and rye fungus and were thought to be responsible for the convulsions, mental confusion, and gangrenous changes in the lower limbs associated with the periodic outbreaks of St. Anthony's fire caused by infected rye in the Middle Ages. All ergot alkaloids can be hydrolyzed to lysergic acid, and various derivatives of this compound have been developed. The diethylamide was synthesized by Stoll and Hofmann in 1938; in 1943 it was discovered by Hofmann to be a potent hallucinogen.

LSD is more than 8,000 times more potent on a dosage basis than mescaline. Less than 0.3 gm. has caused death in status epilepticus of a 7,000-pound elephant. This remarkable substance is by far the most powerful psychotogenic agent known, effective at levels as low as 1 μ gm. (0.000001 gm.) per kilogram of body weight in man. Originally used experimentally to produce an artificial psychosis resembling an acute schizophrenic reaction lasting several hours, it has rapidly become widely employed as a psychedelic agent by a variety of practitioners, and the basis for a growing cult of sorts.

The temporary psychosis caused by a dose of 100 to 500 μ gm. of LSD may be accompanied by almost any type of psychopathology. Suicidal attempts have been known to occur if panic or depression is predominant. Many individuals manifest some degree of subjective euphoria and a sense of great mental clarity

FIGURE 1. Some hallucinogenic indole amines.

FIGURE 2. More complex hallucinogenic indole alkaloids.

or comprehension following the initial marked sympathomimetic effects of the drug, although objectively they may be confused, uncoordinated, hallucinating, and disoriented. Upon recovery, there is often a feeling of being reborn after a profoundly moving and significant experience, and there is often a sense of deep camaraderie with others who were present and participating in the ceremony.

Overdoses of substances like LSD may produce delirium or (rarely) convulsions. The phenothiazines, especially the high dosage group (promazine, chlorpromazine, chlorprothixine, thioridazine) are quite effective antidotes to the effects of these drugs and are preferable to the barbiturates and minor tranquilizers. Thioridazine may be the medication of choice if convulsions are feared in a given case.

Prolonged psychopathological reactions to LSD (that is, lasting more than 24 to 48 hours) are best viewed as latent psychiatric disorders precipitated or exacerbated by the drug experience. Such an illness should be treated basically the same way as in regular clinical practice.

Piperidine derivatives. Both belladonna- and stramonium-containing anticholinergic compounds, such as atropine, scopolamine, and hyoscyamine, have been known for centuries to produce organic psychoses with hallucinations. Cocaine, belonging to this same family, produces hallucinations and thought disorders if taken in toxic doses. These agents are perhaps not properly termed hallucinogens (as previously defined) because the effects depend on overdosage. However, a number of compounds have been synthesized and tested recently by Abood and others in which the substituted glycolic acid side chains are *meta* instead of *para* to the nitrogen of the piperidine ring. These changes have resulted in a large series of psychotogens, including 1-methyl-3-piperidyleclopentylphenylglycolate (the most powerful) and Di-tran (the best known). These compounds can cause delusional thinking, disorientation, and hallucinations.

Another recently synthesized piperidine derivative that has generated much interest is Sernyl. Originally it was thought to be an analgesic or an agent which prevented sensory impulses from reaching nerve centers. Various research groups subsequently described its effects in lower doses as mimicking the primary (Bleulerian) signs of schizophrenia, including flattened affect, thought disorder, and emotional withdrawal, without the secondary signs, such as delusions and hallucinations. This was considered to be due to a peculiar effect on the sensory synapses.

FIGURE 3. A model of the piperidine-derived glycolate series.

FIGURE 4. The major phenylethylamine hallucinogen.

More recent work has led to other reports of behavioral aberrations induced by Sernyl, including phenomena resembling those resulting from sensory deprivation.

Phenylethylamines

Mescaline. The most significant member of this group is the trimethoxyphenylethylamine, mescaline, named after the Mescalero Apaches, who developed the cult of peyotism. Mescaline is the major active component of the buttons from the peyote cactus *Lophophora williamsii*. Today these peyote buttons are chewed by Indians of a number of tribes in the southwestern United States to induce hallucinatory states in their religious rituals. The standard employment of peyote buttons in ceremonies of the Native American Church makes control of their distribution difficult, since freedom of religion is involved.

Mescaline must be administered in high dosage to achieve a full effect, usually 0.5 to 0.6 gm. orally. The experience is usually ushered in by 1 to 3 hours of flushing, vomiting, cramps, sweating, and other autonomic phenomena, followed by several hours (to days in some cases) of visual hallucinations (often colorful), depersonalization, and distortions of time.

The remarkable sensory and introspective effects of mescaline have long fascinated psychopathologists: both S. Weir Mitchell and Havelock Ellis reported personal experiences with it more than 70 years ago. Aldous Huxley, in his *Doors of Perception*, described mescaline intoxication as providing a voyage to the antipodes of the mind.

Amphetamines. Another phenylethylamine group, the amphetamines, should be mentioned in passing, although the therapeutic and addictive properties of these sympathomimetic amines are properly discussed more extensively elsewhere. Chronic administration of large amounts of amphetamine may result in a psychosis with delusions, hallucinations, and dangerous behavior, accompanied by distortions in reality testing. Sleep deprivation, due to the drug's analeptic effects, may contribute to the syndrome. Such reactions usually remit promptly upon withdrawal of the amphetamine, although treatment (including phenothiazine medication) may be required.

Adrenochrome. A trihydroxyindole called adrenochrome (an oxidation product of adrenaline), has been reported by some workers to be hallucinogenic in intravenous dosages of 0.5 mg. Based on these reports (including the supposed discovery of the presence of increased amounts of this and related metabolites in

FIGURE 5. Cannabinol.

body fluids of psychiatric patients), an adrenochrome theory of schizophrenia was advanced by Hoffer and Osmond. More recent studies have failed to confirm the proposition that adrenochrome is an autogenous psychotogenic substance. However, other, more elaborate work on the role of biogenic amines in the human brain may yet prove to be of significance in the search for hallucinogenic or psychotogenic substances related to errors of metabolism in man.

Cannabinols. Although they have been well known since ancient times as perceptual distorters, the members of this psychically active drug family are perhaps not properly defined as hallucinogens. Called hashish, bhang, kif, marihuana, and various other names, these hemp-derived alkaloids produce excitation, vivid imagery, euphoria, and occasionally depression and social withdrawal. More major effects, such as disorientation and true hallucinations, usually occur only with overdosage or prolonged use. The smoking of marihuana (the active agent of which is tetrahydrocannabinol) in cigarette form ("sticks" or "joints") has become quite common in the United States among many groups ranging from criminals to professional musicians to college students (who call it "weed," "pot," "tea," or "Mary Jane"). A recent survey at a major university indicated that perhaps 20 per cent of the student body had used marihuana at least once during the year of the study.

Mechanisms of Action

Electrophysiological. Electrophysiological changes associated with the administration of psychotogens may be useful in understanding their mechanisms of action. Whether recorded from the cortex or the depths of the brain, most of the hallucinogens move spontaneous electrical activity of the central nervous system toward an alert or arousal pattern. Himwich, in a large series of studies of psychotogens, found consistent cortical alerting patterns with active congeners, but these were apparently dependent on intact lower brain stem cortical connections. The nonpsychotogenic congeners could produce an alerting effect even with these connections severed, thus suggesting action at the level of midbrain or higher sites. Adey and co-workers have shown persistent hippocampal electrical changes, resembling those seen in orienting, with low dosage of LSD. Marrazzi has employed transsynaptic excitability as a criterion, measuring evoked cortical potentials from a homologous area on the opposite hemisphere.

Many chemicals that are alerters of the electrocorticograms inhibit or reduce the transcallosal evoked potential. This suggests that what appears by some electric criteria to be an increase in excitability may actually be functional inhibition of opposing systems. Winters has described a continuum of reticular-cortical excitability from arousal to excitatory-occlusive blocking and disorganization under the influence of certain excitatory drugs, with staring and hallucinatory-like posturing of experimental animals during the maximum drug effect.

West has formulated a general theory of hallucinations that predicts their occurrence under a variety of circumstances when sensory input is impaired while arousal is increased. The combination of cortical arousal and impaired sensory input leads to the emergent awareness of ongoing information processing by the brain, the so-called preconscious stream, which is then appreciated by the individual in experiences ranging from fragmentary images to well developed scenarios. The combination of LSD's effects as a sensory poison (it alters retinal cell excitability and electrochemical activity at the sensory synapses) and as a cortical arouser may account for its hallucinogenic characteristics.

Biochemical. Biochemical research in the area of mechanisms of action of the hallucinogens has been growing, but consistent correlates have not yet been established. This may, in part, be because one is dealing with a large number of biochemical phenomena, perhaps different for each drug in spite of similarities in their induced behavioral changes. In addition, the theoretical biochemical models being explored are not easily integrated with behavioral models; the clinician is more likely to feel comfortable when considering formulations from neurophysiology. Such words as alerting and arousal, which appear to have meaning in both the physiological and behavioral realms (even though they may refer to both related and nonrelated phenomena), are not as available in current neurochemical theory.

A number of the hallucinogens apparently undergo metabolic conversions to more active compounds in the body. Szara has done a series of studies on enzymes and urinary metabolites; his results suggest that 6-hydroxylation converts the indole alkylamines to psychoactive metabolites. Mescaline apparently is less active than the products of its oxidative deamination, the trimethoxyphenylethanol and aldehyde. Psilocybin is hydrolyzed to psilocin quite rapidly. The significance of the oxy and hydroxy metabolites of LSD has not yet been evaluated.

Effects on neurohormones. The major theme in research on the biochemical mechanisms of the action of hallucinogens centers around their effects on various postulated neurohormones, including 5-hydroxytryptamine (5-HT or serotonin), norepinephrine, dopamine, histamine, acetylcholine, and a brain polypep-

tide called "substance P." A series of studies of the interaction of LSD and serotonin could be used as representative of this approach.

Gaddum first reported a marked antagonism between LSD and serotonin in their effects on peripheral structures; LSD blocked the smooth muscle contraction effect of serotonin. Because of the structural similarities of these and other substances, it was subsequently postulated by Woolley that antimetabolites of serotonin (whether naturally occurring or artificially administered) may prevent the normal functions of serotonin from being accomplished, with psychopathological results. After Brodie demonstrated that serotonin levels were not depleted by LSD and that the reserpine-produced depletion of brain serotonin was not altered by LSD pretreatment, he postulated that LSD blocked serotonin receptor sites. However, a number of more potent blockers of serotonin's action on peripheral structures were subsequently synthesized in the lysergic acid series, but these blocking agents were not hallucinogenic.

More recent studies by Freedman and co-workers showed that LSD produces a consistent increase in the particle-bound fraction of serotonin, but the nonpsychotomimetic lysergic acid congeners are not as effective. These increases are greatest in the brain stem, mesencephalon, hypothalamus, and medial thalamus. That these changes may be significant is suggested by the fact that alterations in the LSD effects on autonomic and behavioral variables are produced by pretreatment with drugs, such as monoamine oxidase inhibitors and reserpine, which respectively increase and decrease brain amines. Similar studies of drug effects on total brain levels, regional distribution, and bound-free partitioning of serotonin and norepinephrine have been carried out with the use of the indole alkylamines and mescaline.

Acetylcholine has been implicated in the action of some hallucinogens. LSD has been shown to be an inhibitor of both pseudocholinesterase and true cholinesterase. The piperidylglycolates are antagonists of the action of acetylcholine on smooth muscle and are structurally similar to acetylcholine. Histamine levels in the brain have been shown to be reduced by LSD, but the bound form appears to be increased.

Effects of methyl groups. A recent chemical theory of psychosis and psychotogens is related to the presence of methyl groups in both mescaline (a trimethylated hydroxyphenylethylamine) and the *N,N*-dimethyltryptamines (methylated at nitrogen). Mescaline can be related to catecholamine metabolites, and the substituted tryptamines have the potential of coming from tryptophan. These characteristics have suggested to Smythies and others that hypermethylation of naturally occurring amines may make them more accessible to the central nervous system, which would result in the conversion of a peripherally active compound to one that, following hypermethylation, would

penetrate the blood-brain barrier, becoming centrally active and perhaps psychotogenic.

The search for these hypermethylated compounds in the urine of psychotics has been unrewarding except for the recent finding by Friedhoff and Van Winkle of dimethoxyphenylethylamine in the urine of schizophrenics in much higher incidence than in normals. They have also shown that this substance is made from dopa by liver from schizophrenic patients. Although at first reported to produce catatonia in cats, dimethoxyphenylethylamine in rather large dosages in man did not prove to be psychotogenic, although it was *not* given in the presence of a monoamine oxidase (MAO) inhibitor, an experiment that should be attempted.

Another interesting series of experiments by Kety and others, related to the hypermethylation hypothesis, indicated that loads of methionine (and other methyl donors) and tryptophan (following pretreatment with an MAO inhibitor) produced exacerbations of symptoms in schizophrenics. Whether this was a complex, toxic psychosis instead of an exacerbation of the underlying disease remains to be fully explored.

Effects of amines. Recent demonstrations of increased amine stores produced by hallucinogens may explain the chemical basis for their neurophysiological excitation of those brain stem and hypothalamic systems associated with arousal, information scanning, regulation of readiness, and ability to integrate sensory information. As neurochemical horizons expand, in all likelihood such broad categories as amines and such parameters as amount will give way to more specific physicochemical findings, with behavioral phenomena being the final common pathway of a number of different underlying mechanisms.

Screening Techniques

The pharmacological screening techniques for potential psychotogenic compounds are of interest. The most sensitive and pertinent technique for evaluation of these substances is the response of the human experimental subject, especially if care is taken to control for placebo and mental set or suggestive effects. Other efforts to get at these phenomena in man include questionnaires, interviews, and observations by trained observers.

Animal screening tests include check lists of behavior patterns, including aggressivity, excitement, and sociability. More standardized criteria for effects on animal behavior include performance tests like rope climbing and pole walking; activity levels in an activity wheel; blocking of learned avoidance responses and depression of positive instrumental responses; indicators of emotionality such as urination and defecations in a strange environment; and changes in body temperature, because some psychotomimetics produce hyperthermia. Psychotogenic substances have also been found to affect such behaviors as web-spinning

patterns in spiders and swimming patterns in Siamese fighting fish.

Use of Hallucinogens

Nontherapeutic use. The growing use of hallucinogens is worthy of special attention from the psychosocial point of view. Near many a college campus one may find small gatherings of young people in relatively characteristic costumes quietly talking of liberal causes, pop art, and avant garde theater, intermixed with periods of incoherence or sustained staring, against a background of modern jazz music, while smoking "pot," or perhaps sharing a mutual semi-mystical experience under the influence of black market LSD. The observer wonders if this isn't a modern, secular, pharmacologically more sophisticated version of peyotism in the Native American Church, where groups of Indians under the influence of mescaline wait together through the night for intermittent religious visions.

Marihuana. The issue of marihuana is discussed in more detail under drug addictions, perhaps improperly so, since it is not truly an addicting substance. Nevitt Sanford has commented, "Only an uneasy Puritanism could support the practice of focusing on the drug addicts (rather than on our five million alcoholics) and treating them as a police problem instead of a medical one, while suppressing harmless drugs such as marihuana and peyote along with the dangerous ones." On the other hand, it cannot be denied that many anti-social activities include "Mary Jane" as a partner and that the great majority of addicts to substances like heroin and many of those who now use LSD started out by using marihuana. Nevertheless there are many who believe that marihuana should be legalized and made available freely on a commercial basis, like alcohol, for those who wish to use it.

LSD. LSD presents a somewhat different problem, one of importance to medicine and social psychiatry. The use of LSD is increasing, in spite of stringent restrictions upon its distribution, since it is easily synthesized from commercially available starting materials and a growing demand exists. The drug seems to have a particular fascination for intellectuals from the middle and upper classes, many of whom have organized a whole way of life around its use.

It would be an oversimplification to say that all those who are involved in LSD cults of one kind or another are necessarily motivated by a pathological desire to withdraw from reality. The experience is too variable and too complex for such an explanation to hold true; contacts with many LSD users convince the observer that their motives range widely. These motives may include an adventuresome desire to seek new experiences, a craving for shared forbidden activity in a group setting to provide a sense of belonging, a manifestation of adolescent and postadolescent rebelliousness, a simple search for sexual opportunities, a genuine attempt to achieve greater self-under-

standing and self-fulfillment, the exercise of a truly mystical bent in persons with a philosophical orientation inclined toward the transcendental, and, as Blum has described it, the search for fulfillment of a private utopian myth.

Therapeutic use. In addition, of course, there is the inevitable variety of clinical psychiatric patients who are searching for treatment or relief through the use of chemicals. Their desire may be related not only to a magical hope for cure, enhanced by the reputation of a substance as mysterious and extraordinary as LSD, but also to a very understandable human wish for a short cut to therapeutic insight, with considerable saving of time, money, and suffering.

The physician may be tempted in some such cases to go along with the subject's request for one or more treatments with LSD. Before yielding to this temptation, however, he would do well to remember that there are other therapeutic maneuvers, such as hypnosis and the Amytal interview, which have been employed to bypass conscious resistance or temporarily modify ego structure and for which there were once high hopes indeed. Although valuable, these methods have in the long run been found to be of limited general application.

In the use of LSD, as in all instances where powerful drugs are employed, it is important for the clinician to have behind him a solid understanding of both pharmacological and psychodynamic factors, sufficient experience to evaluate the effects of the treatment, and a clear cut formulation of clinical indications and contraindications for the use of the medication in question. There is also a question whether repeated large doses of LSD in certain individuals may lead to apparently irreversible personality changes.

In respect to indications and contraindications, the therapeutic use of LSD and other hallucinogens certainly remains unclear. Among the conditions for which LSD therapy has been tried are alcoholism, narcotic addiction, homosexuality, criminal behavior, various neurotic symptoms, schizophrenia, and resistance in psychotherapy. However, many of these experiments are characterized by vagueness of the therapeutic rationale and poorly controlled clinical conditions. This, in addition to the rare but disturbing prolonged psychotic reactions to these drugs, has led to serious questions about their usefulness in treatment and makes their place in the psychopharmaceutical armamentarium dubious to say the least. Yet the possibility remains that certain individuals may benefit from controlled psychotic-like experiences in which primary process information floods the awareness to produce a self-realizing effect. Therefore, careful clinical research on the therapeutic potentialities of LSD should continue.

Suggested Cross References

More detailed discussions of the biochemical and psychopharmacological topics mentioned here may be

found in the sections by the Himwiches in Chapter 2 on basic biological sciences. The various chemical hypotheses regarding the causes of schizophrenia are discussed in detail by Weiner in his section (Section 15.3) in the chapter on schizophrenia.

5.5 SENSORY DEPRIVATION

PHILIP SOLOMON, M.D.

History

Instances of aberrant mental behavior in explorers, shipwrecked sailors, and prisoners in solitary confinement have been known for centuries. Toward the end of World War II, startling confessions induced by brainwashing in prisoners of war caused a rise of interest in the psychological phenomena brought about by deliberate diminution of sensory input in the human individual.

To test the hypothesis that an important element in brainwashing was prolonged exposure to sensory isolation, Hebb and his coworkers in Montreal brought solitary confinement into the laboratory and demonstrated that volunteer subjects, under conditions of visual, auditory, and tactile deprivation

for periods of up to 7 days, reacted with increased suggestibility. Some of the subjects also showed symptoms that have since become recognized as characteristic of the sensory deprivation state: anxiety, tension, inability to concentrate, vivid sensory imagery—usually visual, sometimes reaching the proportions of hallucinations with delusory quality—and intense subjective emotional accompaniment.

Impressed by these results, Lilly went further and, in an attempt to reduce sensory excitation to as near zero as possible, immersed subjects in a tank of tepid water, having them breathe through a blacked out head mask. Symptoms occurred earlier and more intensely. At Boston City Hospital, the tank-type respirator was used to produce sensory deprivation and monotony, with the advantage that polygraphic recordings from the subject became feasible. Soon, many laboratories around the country and in Canada were setting up similar experiments, and in 1958 a national symposium on the subject was held.

Experimentation

Interest in sensory deprivation became widespread for many reasons. It was intriguing to think that simply doing nothing and being cut off from the outside world could bring about a transient psychotic-like state. Experimental psychoses could be produced heretofore only by drugs, toxic states, or other heroic measures. Theoretical considerations led to various hypotheses of basic psychological interest that could be tested by exposure to sensory deprivation. Among the parameters studied were physiological stress, cognitive functioning, creativity, imagery, personality type, motivation, suggestibility, learning, and state of consciousness. Possible applications could be recognized in such fields as clinical medicine, psychiatry, public health, industrial psychology, and military life.

Unfortunately, from the earliest reports it became evident that there was often considerable disparity in the results from different laboratories. Prolonging sensory deprivation did or did not modify certain cognitive abilities; intensifying deprivation did or did not increase hallucinatory-like experiences; either visual, auditory, or tactile deprivation was predominantly important. Acrimony thus crept into the field.

Thoughtful workers began to study basic differences in methods. Interest focused on choice of subject (the covert selection factor in the volunteer), instructions to the subject (the role of suggestion), novelty (and anxiety) in the experimental set up, breaks in sensory deprivation (feeding, talking, moving), length and type of deprivation (isolation room, water immersion, or iron lung), and other variables. Attempts were made to assess the effects on the subjects of concomitant immobilization and social isolation. Efforts to use the same subject in different laboratories were of little avail. Finally, it was recognized that

quantification would somehow have to be introduced before it would be possible to standardize techniques and understand the apparent discrepancies in the results of different investigators.

It may be concluded that, although much has yet to be learned about the effects of specific individual and experimental variables, sensory deprivation can definitely lead to deleterious effects on the psychological functioning of human subjects. The implications of this fact are relevant to many areas of psychiatry.

Mechanisms of Action

Two kinds of explanations are given for the phenomena of sensory deprivation, one psychological, the other physiological.

Psychological theories. Psychological explanations were anticipated by Freud, who wrote: "It is interesting to speculate what could happen to ego function if the excitations or stimuli from the external world were either drastically diminished or repetitive. Would there be an alteration in the unconscious mental processes and an effect upon the conceptualization of time?" This prophetic stab is an example of Freud's extraordinary and astonishing insight and intuitive faculty. It has, indeed, developed that, under conditions of sensory deprivation, suppression of the secondary process (perceptual contact with reality) brings about emergence of the primary process (regression, confusion, disorientation, fantasy formation, primitive emotional responses, hallucinatory activity, and pseudopathological mental reactions).

Physiological theories. Physiological explanations, though they sound more scientific with their neuro-anatomical terminology, are equally speculative. Presumably the maintenance of optimum conscious awareness and accurate reality testing depends on a necessary state of alertness, which, in turn, depends on a constant stream of *changing* stimuli from the external world, mediated through the reticular activating system. In the absence or impairment of such a stream, as occurs in sensory deprivation and in sensory monotony, alertness falls away, direct contact with the outside world diminishes, and the balance of integrated activity tilts in the direction of increased relative prominence of impulses from the inner body and the central nervous system itself.

Reverberating circuits from the association areas and proprioceptive systems, previously inhibited and kept from greater spread by the exteroceptive and activating systems, find themselves released and able to dominate the brain. The result is an increased tendency to rehearsal of memory, meditative thought, reverie, and body image awareness. Material previously repressed and relatively unconscious is given an impetus to appear in consciousness. The breakthrough, when it occurs, is thus experienced as unwilled or spontaneous, since the material involved has

been stored relatively inaccessible to willful utilization.

Areas of Application

Industrial and military psychiatry. As the phenomena of sensory deprivation become more widely known, it is evoked increasingly to explain puzzling industrial and military accidents. Reference has already been made to its pertinence in brainwashing; it has also been implicated in plane crashes due to grayout and in truck crashes on long hauls over monotonous superhighways. Modern architecture applied to industrial and business plants sometimes has the deleterious effect of producing an environment devoid of sensory stimulation for workers. Assembly line production may bring about similar results, with increased accident rates.

General hospital psychiatry. In the general hospital, the psychiatrist is often consulted in reference to transient psychotic states that appear in conjunction with certain specific treatment procedures in various branches of medicine.

Neurology. Patients with respiratory paralysis treated in a tank-type respirator have long been known to experience peculiar hallucinatory states, which disappear promptly on the patient's removal from the respirator. These states are now recognized to be produced by sensory deprivation.

Medicine. Patients with so-called cardiac psychosis may be suffering from the effects of sensory deprivation. Elderly decompensated patients may be found wandering in the corridors of the hospital at night, when the wards have become quiet. They are usually confused and think they are at home. Too much rest, silence, solitude, and darkness loosen the patients' hold on reality and make them prey to fantasy. Arthritics and other chronic invalids too carefully protected from environmental stimulation may be afflicted similarly.

Ophthalmology. Black patch psychosis, which occurs postoperatively in patients following cataract or other eye operations, is often characterized by a frenzied confusion and disorientation. Bandaging only one eye or allowing a central peephole is usually corrective or preventive.

Orthopedics. Patients in total body casts or immobilized by head tongs or other severely restricting apparatus may develop disturbing psychotic behavior. The provision of frequent visitors, radio, and television is effective in relief.

Surgery. Postoperative isolation in exaggerated form, especially in open heart cases, can bring about the complication of postoperative psychosis. Apparently, sensory deprivation must be avoided assiduously, like wound infection.

Mental hospital psychiatry. The element of sensory deprivation is surely important in delirium tremens, where the best sedative is a sympathetic, attentive nurse. It is probably also a vital factor in the

deterioration of the chronic back ward inmate. When sensory deprivation is neutralized by the many attentions that accompany a new drug study, some previously neglected patients seem to get well.

Developmental psychiatry. In addition to cutaneous stimuli, variegated sensory environment is necessary for the normal development of the infant. Mental retardation may be the result of sensory deprivation as well as of biochemical or physiological factors. Animal studies have shown that early sensory deprivation leads to lowered resistance to stress in later life.

Geriatric psychiatry. Psychological functions in the elderly may deteriorate as the result of pitiful social isolation and sensory deprivation. An increasing number of persons among the elderly live out their lives in single, desolate, barren rooms.

Psychiatric treatment. Results of studies by Azima, Harris, Cohen, and other workers have shown that sensory deprivation can make some psychotic and depressed patients more susceptible to certain treatment methods. The associated regression, for example, favors the anacletic approach.

Conclusion

It has been said that mankind has suffered three major mortifications in its history: Copernicus forced the realization that the earth was not the center of the universe; Darwin stung man with the revelation that he was not created uniquely but evolved from lower animals; and Freud shook man's ultimate conceit, his mind, by showing that much of its vaunted value derived from *unconscious* elements. In a sense the results of sensory deprivation studies may be considered a corollary of this last, in that even man's *conscious* mind can now be seen to be intimately dependent on continuous changing stimuli from the outside world.

Suggested Cross References

For a discussion of the psychotic-like states produced by drugs, see Mandell and West's section (Section 5.4) on hallucinogens in this chapter. Also see Shagass's section on the experimental neurosis (Section 5.3) for more material regarding experimental psychopathology. The various fields in psychiatry and medicine mentioned in this section, such as geriatric psychiatry and psychiatric treatment, are presented in greater detail in Areas J and G, respectively.

Normality

5.6 CONCEPTS OF NORMALITY IN PSYCHIATRY

DANIEL OFFER, M.D.

MELVIN SABSHIN, M.D.

Psychiatrists have always been interested in psychopathology and abnormality. Only recently, however, has there been a concerted effort to define mental health and normality. By and large, previous

textbooks of psychiatry have omitted references to normal or healthy behavior. There has been an implicit understanding that mental health could be defined as the antonym of mental illness. Given such an assumption, the absence of gross psychopathology was often equated with normal behavior. A number of recent trends have cast doubt on the usefulness of this assumption and have made it increasingly important for psychiatrists to become concerned with providing more precise concepts and definitions of mental health and normality.

As psychiatrists have moved out of their consult-

ing rooms and hospital wards into the community, they have come into contact with segments of the population not previously seen. The broader acceptance of preventive psychiatry, including primary prevention, has necessitated a reexamination of preventing *what* in *whom*. Psychiatrists have also become increasingly involved in agency consultation; they are called on to make decisions about who is healthy rather than to decide who is too sick for various positions. Interest in evaluating the outcome of psychiatric therapeutic endeavors has also brought the issue of mental health into focus. Indeed, one of the weaknesses of much work on assessing therapeutic outcome has related to lack of clarity regarding the concepts of normality and mental health.

This section attempts to clarify some of the conceptual issues related to normality and mental health. It cannot provide a definitive answer to the question, "What is mental health or normality?" Such an answer must evolve out of new research and new experience. It does attempt, however, to delineate the current perspectives of normality and to point to new directions that give promise of elucidating the issues still further.

Four Perspectives of Normality

The many theoretical and clinical concepts of normality seem to fall into four functional perspectives of normality. Although each perspective is unique and has its own definition and description, the perspectives do complement each other, so that together they represent the total behavioral and social science approach to normality. The four perspectives are: (1) normality as health, (2) normality as utopia, (3) normality as average, and (4) normality as process.

Normality as health. The first perspective is basically the traditional medical psychiatric approach to health and illness. Most physicians equate normality with health and view health as an almost universal phenomenon. As a result, behavior is assumed to be within normal limits when no manifest psychopathology is present. If all behavior were to be put on a scale, normality would encompass the major portion of the continuum, and abnormality would be the small remainder.

This definition of normality correlates with the traditional model of the doctor who attempts to free his patient from grossly observable signs and symptoms. To this physician, the lack of signs or symptoms indicates health. In other words, health in this context refers to a *reasonable* rather than an *optimal* state of functioning. In its simplest form, this perspective is illustrated by Romano, who states that a healthy person is one who is reasonably free of undue pain, discomfort, and disability.

Normality as utopia. The second perspective conceives of normality as that harmonious and optimal blending of the diverse elements of the mental

apparatus that culminates in optimal functioning. Such a definition emerges clearly when psychiatrists or psychoanalysts talk about the ideal person or when they grapple with a complex problem of discussing their criteria of a successful treatment. This approach can be traced directly back to Freud, who, when discussing normality, stated, "A normal ego is like normality in general, an ideal fiction."

Although this approach is characteristic of a significant segment of psychoanalysts, it is by no means unique to them. It can also be found among psychotherapists in the field of psychiatry and among psychologists of quite different persuasions.

Normality as average. The third perspective is commonly employed in normative studies of behavior and is based on a mathematical principle of the bell-shaped curve. This approach conceives of the middle range as normal and of *both* extremes as deviant. The normative approach based on this statistical principle describes each individual in terms of general assessment and total score. Variability is described only within the context of total groups, not within the context of one individual.

Although this approach is more commonly used in psychology and biology than in psychiatry, psychiatrists have been using pencil and paper tests recently to a much larger extent than in the past. Not only do psychiatrists use the results of I. Q. tests, the Rorschach test, and the Thematic Apperception Test, but they also construct their own tests and questionnaires. Conceptually, the normality as average perspective is similar to Kardiner's basic personality structure for various cultures and subcultures. In developing modal personalities for different societies, one assumes that the typologies of character can be statistically measured.

Normality as process. The fourth perspective stresses that normal behavior is the end result of interacting systems. Based on this definition, temporal changes are essential to a complete definition of normality. In other words, the normality-as-process perspective stresses changes or processes rather than a cross-sectional definition of normality.

Investigators who subscribe to this approach can be found in all the behavioral and social sciences. Most typical of the concepts in this perspective are Grinker's thesis of a unified theory of behavior and Erikson's conceptualization of epigenesis of personality development and the seven developmental stages essential in the attainment of mature adult functioning.

New Directions in Studies of Normality

Although there is growing awareness of the importance of clarifying the various perspectives on normality, there is also an increasing effort to develop empirical research in this area. These new developments are seen in almost all aspects of behavioral science, but the following areas are most prototypic

of the new directions: (1) psychoanalysis, (2) human development, (3) social and community psychiatry, and (4) psychiatric research.

Psychoanalysis. In addition to their growing involvement in linking normality and social process, psychoanalysts have continued their long term interest in elucidating the vicissitudes of normal psychopathology of everyday life. Psychoanalysts have increasingly demonstrated their interest in normal adaptation to the social environment.

Hartmann has given primary leadership to this trend in his conceptualization of autonomous functions of the ego and the ego's conflict-free sphere. The concept of autonomous and conflict-free functions of the ego has intensified clinical exploration of the mechanisms whereby some individuals lead a relatively normal life in the presence of extraordinary external traumatic experiences. In discussing the average expectable environment, Hartmann has provided a framework wherein the molding of character structure for specific contexts becomes more easily understood.

Erikson's work has also served as a bridge linking developmental stages and social process. His concept of modal adaptive tasks at phase-specific stages of life not only has provided a process analysis of normal behavior but allows a cross-sectional analysis throughout life. Thus, it becomes possible to establish specific modes of adaptation.

Human development. In the area of human development, Anna Freud has begun to delineate aspects of normal growth and development in children. Like Erikson, she has been interested in empirical research in helping to clarify how the child copes with a variety of adaptive tasks. The field of child development has been facilitated in its growth recently by a number of reports of longitudinal studies (Kagen). The primary point to be emphasized is that massive data is being collected regarding individual growth and development throughout life. Populations not heretofore studied have been examined with depth and precision.

The study of Offer and Sabshin (1963, 1965) on adolescents is prototypic of this trend. They have studied a group of young adolescents throughout their high school years. The group was selected by means of a questionnaire, and psychiatric interviews have been conducted with a modal sample throughout the high school years. One group of normal teen-agers are being studied over a period of time. Studies like this make it possible to formulate a base line of normal adolescent behavior and psychodynamics.

Based on their experience with a sample of adolescent subjects, the authors have formulated an operational definition of normality that is not an absolute one but is descriptive of one type of middle class adolescent population. The criteria best describing the teen-agers are: (1) almost complete absence of gross

psychopathology, severe physical defects, and severe physical illness; (2) mastery of previous developmental tasks without serious setbacks; (3) ability to experience affects flexibly and to bring their conflicts actively to reasonably successful resolutions; (4) relatively good object relationships with parents, siblings, and peers; and (5) feeling a part of a larger cultural environment and being aware of its norms and values.

These authors based their conclusions on studies of typical or modal groups rather than generalizing from their experience with patients, as had been the predominant pattern in the past.

It is important to note that the developmental approach is also being used for adults. Studies of adaptation to marriage, to parenthood, to work, and to leisure activities have become increasingly prominent. Precise empirical studies are being conducted regarding developmental problems in the period of involution and decline.

The development of geriatrics has moved in a more normative direction. The deficit-focusing orientation of earlier studies in gerontology has been replaced to a significant extent by a normative framework that asks, in effect, "How do older people cope with the adaptational tasks of the 60's, 70's, and beyond?"

Social and community psychiatry. The rapid evolution of social and community psychiatry has given even broader possibilities to studying normative populations. As psychiatrists and their collaborators have moved into the community, they have become involved in providing services for and conducting research with populations not heretofore seen by the mental health professionals. Epidemiological investigations have become increasingly precise and sophisticated. One of the pioneering studies in the epidemiology of illness and health was carried out by Leighton et al. This attempt to ascertain the degree of sickness and health in a large population serves as a paradigm for investigations on a variety of target populations. Although a number of models for social and community psychiatry have developed over the past few years, it has become accepted that community psychiatry involves investigation and service to meet the mental health needs of a functional or geographic community.

One important model for such community psychiatry activity is carried out in the Woodlawn Mental Health Center. At this center, studies have been carried out on all of the children entering first grade in the public and the parochial schools within this geographic community. Over a 2-year span, 4,000 first-graders have been studied. The investigators have been interested in the ratings of adaptation and maladaptation by the teachers, the parents, and the mental health researchers for this entire population. They are also interested in carrying out follow-up studies to determine the impact of changes in experi-

mental groups on the ultimate rating of adaptation and maladaptation.

It is impressive to note that this primary preventive approach combines the interest of child development with community psychiatry. This merging of two trends within the mental health field has great promise in helping to clarify definitions of adaptation and normality as well as maladaptation and abnormality.

Psychiatric research. Psychiatric research has shown a resurgence of interest in the question of the use of controls for a variety of psychiatric investigations. Although a number of studies have focused on the emotional problems of volunteers for psychiatric experimentation, there is a general awareness that increased precision is necessary in selecting controls for a specific psychiatric research question. The report by the Group for the Advancement of Psychiatry has documented this specific need.

Although many investigators have become engaged in studies of controls or normal samples in the context of elucidating an experimental question regarding psychopathology, a host of new investigations have been undertaken to study normal populations as such. Grinker's presentation of a sample of homocites is prototypic of this trend. His sample included an overwhelming number of individuals who ordinarily would not have been seen in a psychiatrist's office. They represent well adjusted individuals whose aspirations and capacities fall within a comparable range of each other.

Psychiatrists are studying the ways individuals adapt to a variety of situational stresses. The stresses vary from adjustment to physical illness and physical hardships (such as the astronauts undergo) to adaptation to marriage, parenthood, leisure, and aging. The study by Silber et al. of the normal coping mechanisms mobilized and utilized by adolescents in the transition from high school to college is one example of such a study.

The Future

The trend toward increased study of normative populations can be equally well documented in a variety of other mental health areas. Convergences have already begun to take place, for example, the convergence of community psychiatric studies and child development within an epidemiological framework. Increasing numbers of such convergences will probably take place during the next few decades. It is not yet possible to synthesize these multiple trends either conceptually or pragmatically. Many more studies will be necessary before such an integrating synthesis will be possible. It is likely, however, that such a synthesis will become possible within a decade, at which time the various perspectives and the various empirical studies can be put together into a more meaningful whole (Offer and Sabshin, 1966).

Suggested Cross References

The reader should compare normal human behavior as discussed in this section with the various pathological behavioral manifestations that are described in Area E on psychiatric assessment and in Area F, which deals with the psychiatric disorders.

5.7 NORMAL PSYCHOSEXUAL FUNCTIONING

HAROLD I. LIEF, M.D.

DAVID M. REED, Ph.D.

Human sexual behavior is so diverse and its interrelations with almost every facet of life are so complex that a comprehensive understanding of it is extremely difficult. Understanding has been further complicated by age-old prejudices, myths, superstitions, half truths, and erroneous theories that, under the protective mantle of "science," have bedeviled the serious investigator of human sexuality. The intense emotions surrounding sex have further hampered such investigation.

Definitions

Normal sexual behavior. Extreme or deviant behavior is easier to discern and comprehend than is the usual range of behavior. In sexual behavior, as in medicine, the normal has generally been extrapolated from observations of the abnormal. To deal with this problem by a different method, Kinsey et al. undertook a monumental study of representative samples of the population.

In this chapter, however, normal is not being used primarily in a statistical sense, although knowing how most people behave sexually is obviously useful, or in the sense of social norm, meaning behavior acceptable to people with average attitudes toward sex, codified by law, social institutions, or religion. In any case, the criteria for social norm based on morality, law, and social customs are contradictory. For example, coitus among unmarried partners is morally abnormal but normal by social custom, accepted by law in half the states and disapproved in the other half.

Normal is used here in the traditional medical sense of healthy or nonpathological. More specifically, it signifies behavior that is adaptive not only to the requirements of society but also to the individual's needs for pleasure, growth, and self-realization or enhancement of his capacities for personality development. The difficulties in this approach are clear: (1) The needs of the individual may conflict with the needs of society. (2) The individual's pursuit of pleasure may conflict with his search for self-realization. (3) His pursuits of short range and long range pleasure may conflict with each other. (4) The value system used by the physician or therapist in reaching judgments of healthy or adaptive behavior is determined by his own cultural value orientation and his personal experiences. For these reasons, no one has satisfactorily delineated normal or healthy psychosexual function.

Since the delineation of normality in human sexual behavior is beset with difficulties, clinical experience suggests that any delineation should not be drawn too rigidly or too narrowly. From a clinical standpoint, sexual behavior may be considered normal even when it does not involve exclusively monogamous heterosexual intercourse or the use of stimulation techniques confined to the primary sexual organs or when it does not culminate in the achievement of mutually satisfactory orgasm. Sexual behavior that deviates widely from such delimited standards may not usefully be designated pathological unless the behavior is also compulsive, exclusive, destructive, or accompanied by much anxiety and guilt. Thus, sex outside of marriage, masturbation, and various forms of sexual stimulation involving other than the primary sexual organs may still fall within normal limits, depending on the total context.

Psychosexual. Further complications occur in use of the term psychosexual. A person's sexuality is so

closely entwined with his total personality—affecting his concept of himself, his relations with others, and his general patterns of behavior—that it is virtually impossible to speak of sexuality as a separate entity. The term psychosexual is, therefore, used here to imply personality development and functioning as these are affected by one's sexuality. It is clearly not limited to sexual feelings and behavior alone, nor is it synonymous with libido in the broad Freudian sense.

In Freud's view, all pleasurable impulses or activities are *ultimately* sexual and should, therefore, be called sexual from the start. This generalization has led not only to endless misinterpretations of Freudian sexual concepts by the laity but also to confusion of one motivation with another by psychiatrists. For example, some oral activities are directed toward obtaining food, whereas others are directed toward achieving sexual gratification, but merely because both are pleasure-seeking and both use the same organ, they are not, as Freud contended, necessarily sexual. Labeling all pleasure-seeking behavior "sexual" precludes clarification of motivation. On the other hand, a person may use sexual activities for gratification of nonsexual needs, such as dependent, aggressive, or status needs. Although sexual and nonsexual impulses may jointly motivate behavior, the analysis of behavior depends on understanding underlying individual motivations and their interactions.

Sexual Learning in Childhood

Not until Freud described the impact of a child's experience on his character as an adult did the world recognize the universality of sexual activity and sexual learning in children. This concept has had greater effect on treatment and on education than any of the other sexual theories Freud expressed. If we put the child's learning in a transactional information (general systems theory) model, we can retain many of Freud's clinical insights while abandoning his psychic instinctual model. For example, as Gagnon indicated, the initiation of sexuality may derive not from the child's nature as much as from the sexual interests of the parents and their labeling of certain aspects of the child's behavior as sexual. Certain oral behavior and the learning of bowel control in the child can be reconceived in terms of their later effect on his sexual life, without insisting that these activities are either completely sexual or protosexual from the beginning.

Most of the sexual learning experiences in childhood occur without thought on the part of the parent, but the consciousness of sex usually determines the degree of vigor of play, the frequency of father-child and mother-child contacts, the tolerance for aggression, the reinforcement or extinction of activity or passivity and of intellectual, aesthetic, or athletic interests. As Gagnon says, "The period of contact, the frequency of contact, and the psychological set of the parents

can be expected to have differential consequences for gender role development."

It is clear from direct observation of children in various situations that genital play in infants is part of the normal pattern of development of the healthy child in contact with an affectionate mother. Interaction with mothers and peers is necessary for the development of effective adult heterosexual contacts in monkeys, according to Harlow, a finding that has relevance to the normal socialization of children. There is a critical period in development beyond which the infant may be immune or resistant to certain types of stimulation but during which he is particularly susceptible to the same stimuli. The detailed relation of critical periods to psychosexual development has yet to be established; presumably Freud's stages of psychosexual development—oral, anal, phallic, and genital—are only gross approximations.

Psychosexual Factors

A person's sexuality is dependent on three interrelated factors: his sexual identity, his gender identity, and his sexual behavior. These factors affect his personality growth, development, and functioning, and their totality is here termed psychosexual. Clearly this is something more than physical sex, coital or noncoital, and something less than every aspect of behavior directed toward attaining pleasure.

Sexual identity. Sexual identity refers to a person's sense of maleness or femaleness, which, in turn, depends on his biologic sexual characteristics: chromosomes, external genitalia, internal genitalia, hormonal composition, gonads, and secondary sex characteristics. In normal development these form a cohesive pattern, so that a person has no doubt about his sex.

Modern embryological studies have shown that all mammalian embryos, both the genetically male and the genetically female, are anatomically female during the early stages of fetal life. Differentiation of the male from the female results from the action of fetal androgen; the action begins about the 6th week of embryonic life and is completed by the end of the 3rd month. Sherfey contends that these observations have "demonstrated conclusively that the concept of the initial anatomical bisexuality or equipotentiality of the embryo is erroneous." Sherfey's refutation has far reaching implications regarding normal human sexual responsiveness and alleged causes of homosexuality and other sexual deviations.

By the age of 2 or 3 years, almost everyone has a firm conviction that "I am male" or "I am female." Even if maleness and femaleness develop normally, the person still has the adaptive task of developing a sense of masculinity and femininity.

Gender identity. According to Stoller, gender identity "connotes psychological aspects of behavior related to masculinity and femininity." Gender he considers social, whereas sex is biological; "most often the two are relatively congruent, that is, males tend to

be manly and females womanly," but sex and gender may develop in conflicting or even opposite ways.

"Gender identity results from an almost infinite series of cues derived from experiences with family members, teachers, friends, and co-workers as well as from cultural phenomena. Physical characteristics derived from one's biological sex, such as general physique, body shape, and physical dimensions, interrelate with an intricate system of stimuli, including rewards, punishment, and parental gender labels, to establish gender identity.

Cultural factors, as Cohen has pointed out, may establish conflicts about gender identity by stereotyping certain nonsexual behavior as masculine or feminine: "Our narrow conceptions of what is manly and hence not womanly, of what is womanly and hence not manly (conceptions which exclude large areas of thought and feeling which might appropriately be considered as human rather than narrowly sex-bound) can be seen to give rise to difficulties in our development and our relations with each other and with our children." Artistic or intellectual interests in a boy may be regarded by his parents and perhaps himself as feminine, whereas a girl who strives for competence, intellectual development, and independence may be made to feel uneasy if these activities are labeled masculine.

The formation of gender identity is based on three factors: parental and cultural attitudes, the infant's external genitalia, and a biological force under genic influence, now identified as being physiologically active as early as the 6th week of fetal life. Whereas family, cultural, and biological influences may complicate establishment of a sense of masculinity or femininity, the standard and healthy outcome is a more or less secure sense of identification with one's biological sex, a stable gender identity.

Gender role. Related to and in part derived from gender identity is gender role behavior. This is described in the words of Money and the Hampsons as "all those things that a person says or does to disclose himself or herself as having the status of boy or man, girl or woman, respectively. . . . A gender role is not established at birth but is built up cumulatively through experiences encountered and transacted—through casual and unplanned learning, through explicit instruction and inculcation, and through spontaneously putting two and two together to make sometimes four and sometimes, erroneously, five."

The standard and healthy outcome is a congruence of gender identity and gender role. Although biological attributes are significant, the major factor in attaining the role appropriate to one's sex is learning; the influence of chromosomal and hormonal sex, for example, can be overcome by opposite sex assignment by parents or by other learning experiences.

Gender role can appear to be in opposition to gender identity. A person may identify with his own sex but adopt the dress, hair style, or other characteristics of

the opposite sex (as many of our present teen-agers do). Or a person may identify with the opposite sex, yet for expediency adopt much of the behavior characteristic of his own sex.

Sexual behavior

Masturbation. Masturbation is usually a normal precursor of object-related sexual behavior. In the words of Dearborn, "No other form of sexual activity has been more frequently discussed, more roundly condemned, and more universally practiced than masturbation." Research by Kinsey et al. into the prevalence of masturbation indicated that nearly all men and three fourths of all women masturbate sometime during their life.

Longitudinal studies of development show that sexual self-stimulation is very common in infancy and childhood. Just as the infant learns to explore the functions of his fingers and mouth, so it is inevitable for him to do the same with his genitalia. Pleasurable sensations result from any gentle touch to the genital region. These sensations, coupled with the ordinary desire for exploration of one's body, produce a normal interest in masturbatory pleasure at this time. As the youngster acquires playmates, this curiosity about his and others' genitalia motivates episodes of exhibitionism or genital exploration, and such experiences, unless blocked by guilty fear, contribute to continued pleasure from sexual stimulation.

With the advent of puberty, the upsurge of sex hormones, and the development of secondary sex characteristics, sexual curiosity is intensified and masturbation increases. The adolescent is physically capable of coitus and orgasm but is usually inhibited by social restraints. He is under the dual and often conflicting pressures of establishing his sexual identity and controlling his sexual impulses. The result is a great deal of physiological sexual tension that demands release, and masturbation is a normal way of reducing sexual tensions. An important emotional difference between the pubescent child and the youngster of earlier years is the presence of coital fantasies accompanying masturbation in the adolescent. These fantasies are an important adjunct to the development of sexual identity, for in the comparative safety of his imagination the adolescent learns to perform the adult sex role. This form of autoerotic activity is usually maintained into the young adult years, when it is normally replaced by coitus.

It is incorrect to assume that couples in a sexual relation abandon masturbation entirely. When coitus is unsatisfactory or is unavailable because of illness or absence of the partner, self-stimulation often serves an adaptive purpose, combining sensual pleasure and tension release.

Moral taboos against masturbation have generated myths that masturbation causes mental illness or a decrease in sexual potency. There is no scientific evidence to support such claims. Masturbation is a psy-

chopathological symptom only when it becomes a compulsion beyond the willful control of the person. It is then a symptom of emotional disturbance, not because it is sexual but because it is compulsive. Masturbation is almost a universal and inevitable aspect of psychosexual development, and in most cases it is adaptive.

Orgasm. The development of adaptive sexual behavior involves an increasing interest in the opposite sex, first at the level of fantasy and dreams and then in dating and courting. Orgastic behavior for both men and women involves the sexual arousal state followed by four stages, as described by Masters and Johnson: excitement, plateau, orgasmic, and resolution phases.

The sexual motive or arousal state is affected by many factors, such as the partner, the setting, the mood, and the positive or negative effect of emotions (love, anxiety).

When the degree of motivation for orgastic release is high, excitement occurs quickly. In the male, the initial physiological response to effective sexual somatogenic or psychogenic stimulation is penile erection; in the female, it is vaginal lubrication. Lubrication occurs within 10 to 30 seconds and is the result of a sweating phenomenon on the walls of the vaginal barrel.

If excitement is maintained, the intensity of the response usually increases rapidly, and the human male or female enters the plateau phase of the sexual cycle. The duration of the plateau phase again depends on the effectiveness of the stimuli and the strength of the drive for orgastic release.

The orgasmic phase lasts only a few seconds, during which basic responses of the body to sexual stimulation—widespread vasocongestion and generalized increase in muscle tension—are released. Both the intensity and duration of orgasmic experience vary widely in women, whereas in men there is less individual variation.

In men, the resolution phase includes a refractory period that prevents restimulation until its termination. In the female, the potential for multiple orgastic experiences is almost unlimited.

Important findings in the research of Masters and Johnson include the following observations. (1) The nature of the orgasm in women is the same, regardless of the method or zone of stimulation, and it is as definite as it is in men. There is no such thing as a vaginal orgasm distinct from a clitoral orgasm; anatomically and physiologically there is only one type of orgasm: the rhythmic contractions of the outer third of the vaginal barrel, releasing the vasocongestion of the greatly distended circumvaginal venous plexi and vestibular bulbs surrounding the lower third of the vagina. (2) The clitoris retracts about 60 to 90 seconds before orgasm, an essential feature of a mechanism of the clitoral region, which maintains continuous stimulation of the retracted clitoris by a rhythmic

pulling on the edematous prepuce during coition or by preputial friction during direct stimulation of the clitoral region. Clitoral responsivity is far more important than vaginal sensations in producing orgasm. (3) With full sexual arousal, women are normally capable of many orgasms. As many as six or more can be achieved with intravaginal coition, and many more orgasms can be obtained in an hour by direct stimulation of the clitoral region—limited only by physical exhaustion.

Sexual drive and expression is multidetermined and can be profoundly affected by physical and psychological factors. Normal strength of the sexual drive varies widely with age, sex, and the individual. The usual frequency of orgasm in mature men is two or three times a week; women have a much greater and, according to Masters and Johnson, an almost unlimited orgasmic potential. It is a matter of practical importance that there is a disparity in the age-related strength of the sexual drive in men and in women. The peak of sexual drive for men occurs during late adolescence, after which it gradually declines. Women reach the maximum of sexual desire in their 30's, particularly after the birth of one or more children.

Sherfey hypothesizes that the rise of modern civilization "was contingent on the suppression of the inordinate cyclic sexual drive of women because... women's uncurtailed continuous hypersexuality would drastically interfere with maternal responsibilities;... with the rise of the settled agriculture economies... large families of known parentage were mandatory and could not evolve until the inordinate sexual demands of women were curbed."

Social sexual morality, operating primarily through the effect of guilty fear (a sense of wrongdoing and a fear of punishment internalized as a fear of conscience), has impaired the orgasmic potential of many women. Guilty fear and other emergency emotions, such as anxiety, anger, and guilty anger, may delay or completely inhibit orgasm in the female and prevent erection or speed up orgasm in the male. Since emergency emotions increase the disparity between the time it takes to reach orgasm in men and women, hastening it in men and retarding it in women, healthy psychosexual functioning requires minimal or absent emergency emotions and is enhanced by positive or welfare emotions, such as pride, joy, and love. Of these, in the normal person, love for the partner has the greatest effect in increasing sexual pleasure and performance.

Love, Intimacy, and Sex

As we have seen, healthy psychosexual functioning depends on the development of sexual identity, gender identity, appropriate gender role behavior, and adequate sexual performance. It also requires the devel-

opment of the capacity to love and to form intimate relations with a person of the opposite sex. If anything is more complex than sex, it is love. If sex is diversified and varied, love is more so; if sexual behavior is the result of the subtle interplay of multiple motivations and needs, love is more so. If man's capacity to perform sexually may be inhibited by faulty learning and the influence of emergency emotions during childhood and adolescence, even more subject to the vicissitudes of unfortunate life experiences during these formative years is man's capacity to love and to be intimate.

(In a child's healthy evolution into adulthood, the potential for enjoyment of physical sexual sensations and the ability to give and to receive love have interrelated lines of development. It is as if two streams come from a similar source, the headwaters being the love of mother for child, then diverge, cross, become confluent, separate, come together again, and separate again and again until ultimately, in the state of being in love, they fuse again in a crescendo of power and fulfillment.)

Definition of love. A precise definition of love is difficult. Rado defines love as a sustained emotional response to a known source of pleasure. There are as many kinds of love, therefore, as there are types of pleasure, and typical of being in love is a desire to maintain closeness to the love object. This circular definition includes varieties of love besides sexual love, such as parental, filial, fraternal, anaclitic, and narcissistic love, as well as love for group, school, and country. Here we are concerned specifically with love enhanced by sex, and sex enhanced by love. The development of sexuality and the development of the ability to love have reciprocal effects on each other.

Stages of love. As with sexuality, love evolves through a number of stages. In the beginning, since he is dominated by the wish to gratify his needs, the child loves himself. His parents are the principal instruments by which his needs are met; hence, a magical love for his parents appears, a love marked by illusions that parental figures are omnipotent, capable of immediate and complete satisfaction of the child's basic needs, and constant in their love for the child, regardless of his misbehavior. As the child becomes more and more aware of others, he learns the pleasure of object love and gradually is encouraged to feel sympathy, affection, and love toward others in various interpersonal situations. These feelings and related behavior are reinforced by love, praise, and gifts from others. The achievement of object love by the child is the goal of early acculturation, for the ability to cooperate and compromise allows the developing child to acquire satisfactory group behavior, which in turn assures acceptable social patterns in later life.

Although the influence of sex on the development of love begins with the development of early sexual identity, it becomes more evident during development of

gender identity and gender role behavior. As the child is taught in many ways to discriminate between masculinity and femininity, he is also challenged to become aware of differences between men and women in their attitudes toward sex as an expression of love. Boys, for example are encouraged to express sexual love assertively and girls more passively.

Freud made the error, in his libido theory, of thinking that there were fixed quantities of love and consequently that, as in a closed system of energy exchange, the more one loves himself, the less love he has to give another. As Fromm pointed out, however, self-love or self-regard is a fundamental requirement of the capacity to love another, and the two are not mutually exclusive.

When a person is able to give and receive love with a minimum of fear and conflict, he has the capacity to develop genuinely intimate relations with others. When involved in an intimate relation, he actively strives for the growth and happiness of the loved person. Mature heterosexual love is marked by the intimacy that is a special attribute of the relationship between a man and a woman. The quality of intimacy in a mature sexual relationship is what May terms an ability of "active receiving," wherein a person, while loving, permits himself to be loved. This capability indicates a profound awareness of love for another as well as for oneself. In such a loving relation, sex acts as a catalyst. May described the values of sexual love as an expansion of one's self-awareness, the experience of tenderness, increase of self-affirmation and pride, and sometimes, at the moment of orgasm, even loss of feelings of separateness. It is in this setting that sex and love are reciprocally enhancing and healthily fused.

The nuances of the interplay between love and sex in a heterosexual relation reflect strength, not weakness. Persons who establish alliances based primarily on sex, in which each uses the other as an object for orgasmic release and little else, may soon tire of each other. At the opposite extreme, couples attracted to each other primarily for reasons of security, rather than sex, sacrifice a very important aspect of psychosexual experience.

Normal heterosexual love has three major components, called by Rado "sexual," "magical," and "sensual." Sexual love is dominated by the desire for shared orgasmic release. Magical love is surrounded by the expectation that the love object is so powerful and wise that he will provide care and security as effortlessly as one's parents appeared to do in childhood. Sensual love is stimulated by an appreciation of the physical attractions of the loved one and an idealization of them on a highly subjective level. A couple may experience any of these types of love at different times and at different emotional levels, depending on the vicissitudes of life and the proclivities and interactions of the two people. A constant interweaving of

the three types of love is likely to produce the most enduring and fulfilling relation.

Marital and Nonmarital Sexual Relations

Historically, marriage has provided for the fulfillment of sexual desires, the bearing of children, and distribution of wealth. Only relatively recently in the history of man has marriage been undertaken as an act of love; in the past, most cultures arranged marriages primarily on economic grounds. American civilization, under the impact of the Judeo-Christian tradition, has been characterized by a respect for the individual person based on two dominant values, achievement and equality. The result has been the development of a social system that attaches high status and prestige to the person who realizes his highest potentials as a citizen and as a human being. At first, this attitude applied exclusively to men, but in recent generations it has included both sexes.

Indeed, the most profound change in the modern sexual revolution has been traced to the altered role of woman. Whereas woman was once expected to accept a double standard in which man alone was permitted sexual freedom, she is now challenging this male prerogative. There is a strong trend toward the dispelling of psychosexual conditioning that previously made women feel guilty and excessively inhibited in sexual matters. Many observers consider this trend indicative of a future era of sexual freedom in which both sexes will relate on a more equal basis than has been the case in the past.

Choice of love object. The increasing equality of the sexes profoundly affects the choice of love object. A person is attracted toward a potential mate for various reasons. One may be a purely physical attraction, which ordinarily establishes a transient relation. Another may be a magical desire to find the perfect lover, whose qualities will be reminiscent of the idealized qualities of one's parents or other sources of love and affection in the past. Other emotional reasons for choosing a mate stem from a variety of neurotic patterns in one's own personality. For example, one may take a partner to protect pride or security rather than to satisfy feelings of love. A woman who considers herself unattractive sexually may choose a mate who is passive and dependable yet sufficiently unattractive so that she does not have to compete with other women. A man who has considerable doubt about his masculinity may turn to a woman who has great sex appeal on the surface but in reality may not demand exceptional sex drive or performance. Essentially neurotic themes such as these exist in all personalities and probably in all matings. When they predominate and the couple act mainly to exchange patterns of exploitation or when interlocking complementary needs fail to bring sufficient security or happiness, discomfort and anxiety occur, and a breakdown in the relation is possible.

Premarital intercourse. Kirkendall noted that there is no consensus about the effects of premarital intercourse on successful marital adjustment. He found no statistical evidence in favor of premarital sex helping later sexual adjustment but pointed out that a couple's viewpoint toward premarital sex may range from a highly positive one to a very damaging and disruptive one. He also noted that the negative effects on marriage attributed to premarital sex have been exaggerated in our culture, presumably as a result of religious views that equate sex outside of marriage with sin. Just as Kinsey found that the most important social coordinate that had a negative effect on the sexual behavior of women was religion, so did Kirkendall note that those who are reared with a rigid attitude toward sex are likely to experience guilt reactions in either premarital or marital intercourse.

At this point some evaluation of cultural norms is in order. An adaptive sexual relation is possible between partners who are not married. The achievement of healthy intimacy and mutual respect cannot be traced to the ritual of marriage by itself. As many neurotic interactions occur in marriage as outside of it. In view of our cultural disapproval of nonmarital coitus, however, a large number of premarital coital acts may be nonsexually motivated; they may, for example, represent acting out of rebellion against authority. There is, thus, a somewhat greater chance that a premarital sexual relation is partly neurotic in origin than that a marriage is neurotic. This statement requires qualification, however, since certain sectors of our society permit premarital sexual relations with a minimum of guilty fear. Despite the neurotic bases of many marriages, including destructive sexual behavior, the psychological and social assets of marriage are nonetheless inestimable. Marriage can provide the structure for the maintenance of love, intimacy, sexual gratification, and development of family life over many years.

Problems of marriage

Early problems. Many fine romances have been ruined by marriage. In the marriage act couples undertake a psychological transformation. Whereas they may be able to relate sufficiently to each other as single men and women, the moment they are married and undertake the roles of husband and wife and thereby anticipate the roles of mother and father, they encounter unconscious responses to their own parents. The girl friend who becomes a wife must start managing a house, and she usually does this by imitating her mother. In so doing, she may be profoundly influenced by her mother's attitudes toward sexuality which were transmitted to her during her childhood. Similarly, the man who becomes a husband finds himself relying on patterns established by his father in the husband role. If there had been an intense relation between the child and parent of the opposite

sex during the child's formative years, coitus in marriage may be accompanied by intense anxiety, not present in the couple's sexual relations outside marriage. One of the sources of sexual difficulties at this time is the unconscious perception of coitus with one's spouse as incest.

The marital pattern now in vogue in America is subject to certain vulnerabilities. The average age of marriage today for girls is around 19 years; about half the teen-age marriages end in divorce, and nearly one third are complicated by premarital pregnancy. Most observers agree that these marriages are products of a culture that has overemphasized sexual gratification and performance to the exclusion of love, intimacy, and a lasting relation. Our culture may be guilty of the mechanization of sex, of separating sex from love. With the influx of knowledge about the art of coitus and the constant emphasis on the need for adequate sexual satisfaction of one's partner, there is danger, as May pointed out, of creating a culture of sexual athletes. Such persons treat each other primarily as objects for orgasmic release. They function purely on the basis of sexual love, and the relationship may deteriorate as soon as sexual tensions decline and their related needs are gratified. This outcome is the unfortunate fate of many young couples who discover too soon that the honeymoon is over.

Later problems. The passage of time brings different pressures on marriage. Early in marriage, money, sex, in-laws, and the demands for companionship are common sources of conflict and stress. Somewhat later in marriage, childbearing brings into sharp relief conflicts in gender role behavior, and underlying neurotic patterns based on earlier relations with parents. A woman overly committed to her family and home during the period of child rearing may regard eventual separation from her children as an indication of her uselessness (the empty nest syndrome). When marital, especially sexual, relations do not compensate for this loss, additional strain occurs. An aging man's preoccupation with personal success may be accompanied by fears of failing potency.

As couples grow older, sexual relations usually play an important role in maintaining marital stability. For this reason, the findings of Masters and Johnson that the sexual drive of women increases during middle age and that orgasm can be achieved during the 8th decade of life are significant in counseling the aged. These researchers point out that aging women are fully capable of achieving orgasm, particularly if they are exposed to regular and effective sexual stimulation. Aging men are usually able to continue some form of active sexual expression into the 8th and even 9th decades of life. The most important factor in maintaining effective sexuality in men of this age is consistency of active sexual expression. If a man is sexually active through the middle and involutional years, sexual gratification thereafter may be highly satisfactory.

Suggested Cross References

The concept of normality is discussed by Offer and Sabshin in the preceding section. For a discussion of the sexual deviations of adults, see the sections by Bieber (Sections 26.2 and 26.3) and by Lorand and Schneer (Section 26.4) in Area F, on the psychiatric disorders. Other sexual disturbances such as impotence and frigidity are discussed in the sections by Klein (Section 30.8) and by Hastings (Section 30.7) in the chapter dealing with psychosomatic disorders. Work deals with sexual pathology of children (Section 41.6) in Area H, on child psychiatry. Psychosexual development is also discussed by Mack and Semrad in their section (Section 6.1) on classical psychoanalytic theory of personality and psychopathology in Area C.

CURRENT THEORIES OF PERSONALITY AND PSYCHOPATHOLOGY

The term "personality" is used in different ways by different authors. In general, however, it refers to the individual's characteristic behavioral interaction with his environment. Normal personality organization and abnormal psychological functioning (or psychopathology) are closely related and can be considered within similar conceptual frameworks. Many theories have been proposed to explain the structure and dynamics of normal and abnormal behavior. Essentially, these theoretical models are designed to facilitate the understanding, prediction, and eventual therapeutic control of human behavior.

Different theories of personality and psychopathology generally deal with the same basic issues and operate on comparable levels of description. However, they tend to vary in emphasis; they employ different theoretical constructs and are often based on different underlying hypotheses. At the present time, no one theory is able to explain and predict normal human behavior in an entirely satisfactory manner; nor has any single theory been able to account adequately for the many forms of abnormal behavior encountered in clinical practice. Nevertheless, many theories of personality and psychopathology have contributed valuable concepts and methods of treatment.

Brief, but comprehensive, synopses of those theories which exert the greatest influence on current psychiatric thought are presented below in this area, on current concepts of personality and psychopathology. Because authenticity and accuracy are of importance in this complex field, each theory is discussed by one of its eminent exponents.

To facilitate comparison, wherever feasible, each of

these theories is presented from the viewpoint of the following parameters: (1) the structure and development of normal personality; (2) concepts of psychopathology and psychodynamics; and (3) the treatment techniques which have derived from each theory.

Sigmund Freud's role in explaining the motivation of behavior within the framework of his classical psychoanalytic theory was preeminent in the evolution of the psychodynamic approach in psychiatry. In addition to a comprehensive theory of personality, Freudian psychoanalysis provides a method for treatment and research. Classical psychoanalysis has undergone some modifications which reflect recent developments in ego psychology, and the further refinement and elaboration of concepts concerning the structure of the psychic apparatus. On the whole, however, the basic concepts of psychoanalysis, as they were originally elaborated by Freud, remain relatively unchanged and represent the approach of many psychiatrists in the United States today.

At various stages in the evolution of psychoanalysis, several of Freud's colleagues expanded or revised his formulations. At times, these modifications were subsequently incorporated into the body of psychoanalytic theory. However, other innovations produced schisms within the Freudian movement and in some instances led to the establishment of new schools of psychoanalysis.

Among the most prominent of these early "dissenters" were Adler and Jung, both of whom rejected Freud's belief that sexuality plays a unique role in normal and pathological human behavior. Jung's rejection of Freud's libido theory led to the elabora-

tion of a rather mystical psychoanalytic system. Adler turned to the sociocultural determinants of behavior. Social, cultural, and interpersonal behavioral determinants were also emphasized in the so-called "culturalist" theories of Rado, Horney, Sullivan, and Fromm. And concomitantly, these workers deemphasized the biological instinctual drives, particularly sexuality, as dominant determinants of behavior.

Other theories of psychopathology did not evolve as direct offshoots of Freudian psychoanalysis. Among these is the theory of Adolf Meyer, who conceived of normal as well as abnormal behavior as deriving from a series of adaptive reactions to the environment. Meyer's theoretical position, although not represented by an organized "school," has exerted marked influence on American psychiatry. Indeed, in the American Psychiatric Association's standard nomenclature, the psychiatric disorders are termed "reactions," which derives from Meyer's theoretical model. Another theory of interest is existential psychoanalysis, which derives from the application of the concepts of existentialist philosophy to psychoanalysis.

Other theories of personality derive from various aspects of psychology, such as learning theory and the quantitative methods of personality assessment. No

attempt has been made to present a comprehensive survey of this field. Rather, those theories have been selected for discussion which are considered most relevant for psychiatry.

As mentioned above, all of these theories have limitations; no single theory has, as yet, been universally accepted by psychiatrists. Nevertheless, the theories of personality and psychopathology presented below are the foundations upon which the practice of psychiatry rests. Each of these theories contains insights which merit consideration because they enhance our understanding of the complexities of normal and abnormal human behavior. Furthermore, they provide useful theoretical frameworks around which the psychiatrists' clinical work can be organized. Methods of psychiatric assessment, as well as the various treatment methods which are described in Area G, on psychiatric treatment, have evolved from these models. Similarly, current hypotheses that have been proposed to explain the dynamics of the various psychiatric disorders, which are described in Area F, derive from the theories described herein. The different disorders are described according to different psychodynamic theories, another indication of the diversity of theoretical orientation which is characteristic of psychiatry today.

CURRENT THEORIES OF PERSONALITY AND PSYCHOPATHOLOGY

Chapter 6

Classical Psychoanalysis

6.1 • • •

JOHN E. MACK, M.D.

ELVIN V. SEMRAD, M.D.

Introduction

Concepts derived from psychoanalysis are applied so widely in psychiatric training and practice that they have become a fundamental part of our approach to mental and emotional disorders. Obviously, then, it is imperative that the student develop a clear understanding of classical psychoanalytic theory and the work of its founder, Sigmund Freud. Unfortunately, discussions aimed at residents, medical students, and other students of psychiatry, which attempt to facilitate such understanding, are typically impeded by problems arising from the student's lack of familiarity with the principal investigative tool of classical psychoanalysis—free association—and, concomitantly, his limited contact with the data derived therefrom, upon which psychoanalytic theory is based. In fact, the study of psychoanalysis requires a fundamental change in orientation: in contrast to the planned, organized pursuit of data which is characteristic of most fields of medicine, the psychoanalyst does not deliberately solicit specific information from his patient. Rather, psychoanalytic data consist of the patient's spontaneous (and uncensored) verbal expressions. In addition, the student's efforts to understand psychoanalytic theory may be further complicated by the apparent disparity between the formal terminology Freud employed to describe mental and emotional phenomena and the technical language used in other medical and paramedical disciplines. Throughout this discussion, an attempt has been made to define in detail the methods and terminology which are fundamental to classical psychoanalytic theory in order to avoid confusion and misunderstanding.

Scientific orientation. As a result of his early training, Freud came to his work in psychology imbued with the belief, held by most scientists of his

day, that scientific law and order would ultimately permit an understanding of the apparent chaos of mental processes and that brain physiology was the most promising avenue of approach to this objective. By 1897, Freud no longer shared this illusion; however, all his life he continued to believe that there was a close interrelationship between physical and psychical processes, that mind and brain did not exist as separate entities. In addition, he maintained that physical processes preceded psychological phenomena. All information which reached the mind began as physical excitation, whether such information emanated from the external world and was transmitted through the sense organs, or whether it came from the chemical stimuli provided by the body. In his efforts to correlate mental processes with physiological ones, Freud was able to note similarities in the way both operated. However, although he was thoroughly familiar with the language of physiology, he found the task of translating psychological processes into physiological terms an insurmountable one. Nevertheless, he made several attempts to describe mental phenomena in terms of the functioning of the nervous system before he eventually suspended these efforts and decided instead to approach psychological problems on a level of investigation appropriate to their study.

Definition. Traditionally, classical psychoanalysis has referred primarily to Freud's libido and instinct theories; recently, it has come to include the concepts of ego psychology as well. Essentially, it is based on the free association method of investigation which yielded the data used by Freud to formulate the key concepts of unconscious motivation, conflict, and symbolism which formed the basis for his broader theoretical system.

Basic hypotheses. Psychoanalytic theory, like all personality theory, is concerned primarily with the elucidation of those factors which motivate behavior. Psychoanalysis is unique, however, in that it considers these motivating forces to derive from unconscious mental processes. Freud's demonstration of the existence of an unconscious mind and, concomitantly, his concept of psychic determinism are generally regarded as his greatest contributions to science, and these re-

main the fundamental hypotheses of psychoanalytic theory. When it is considered within this theoretical framework, behavior which is inexplicable otherwise can be attributed to specific psychic determinants or goals.

These hypotheses led, in turn, to the elaboration of a third concept which is central to psychoanalytic theory: the mechanism of repression, the selective forgetting of what is too painful or objectionable for the conscious mind to accept. Initially, on the basis of his early clinical experiences, Freud maintained that the significance of repression resided in its relationship to psychopathology; or, more specifically, he believed that there was a relationship between the repression of sexuality and the development of neurosis. While this insight, in itself, was of dramatic import for the future development of psychoanalysis, its true value lies in the fact that it opened new avenues of investigation which, in turn, gave rise to more complex theoretical constructs of greater significance. Thus, Freud's subsequent study of infantile sexuality and his knowledge of adult perversions led him to hypothesize that the sexual instinct may find many forms of expression apart from its final aim of genital union, i.e., coitus, that, in fact, the sexual instinct must pass through a rather complicated developmental sequence before it achieves what Freud called "genital primacy."

Psychoanalytic theory deals with mental structure and the economics of mental functioning, as well as its dynamics. Thus, Freud divided the mind, in a regional or topographical fashion, into the unconscious proper, the preconscious, and the conscious. The study and formulation of these systems of the mind, and of the tripartite model of ego, id, and superego, which represent its structural components, form the basis for the Freudian theory of personality.

Throughout his lifetime, Freud continued to modify and elaborate his original concepts of the psychic apparatus, the dynamics and economics of mental functioning, and the origins and nature of psychopathology. And the open-ended nature of psychoanalytic theory has permitted further modification and elaboration of these constructs by those who followed in his path. The boundaries of classical psychoanalytic theory have not been sharply defined in this section. Rather, an attempt has been made to describe in detail those concepts which are currently accepted by psychoanalysts who have been trained in the classical tradition, and which have particular relevance for students of psychiatry, i.e., Freud's concept of the topography of the mind, the libido and instinct theories, concepts pertaining to the mechanisms of defense and to the nature of anxiety, the psychology of dreams, the significance of early childhood experiences, and, finally, formulations in ego psychology. At the same time, however, it is generally agreed that these formulations can be fully understood only if one traces their historical development. The following discussion

and further elucidation of these basic concepts have been guided by this premise.

Historical Beginnings of Psychoanalysis

Sigmund Freud was born of Jewish parents on May 6, 1856, in Freiburg, a small town in Moravia, which has since become part of Czechoslovakia. When he was 4, his father, a wool merchant, brought the family to Vienna. And it was in Vienna, a city he both loved and hated, that Freud was educated, practiced, and lived his entire life, until he was forced to flee to England in 1938 when the Nazis annexed Austria.

Medical training. Because his education followed a somewhat erratic course, it took Freud 3 years longer than the usual time to earn his medical degree. However, the fact that he was a medical student in the years from 1873 to 1881 is significant. For during this period the researches in biology of Darwin and his associates, and the investigations in physiology and physics by Helmholtz and his school were producing a new scientific climate which played a significant role in Freud's intellectual development. More specifically, this new orientation emphasized natural law, the unity of science, and scientific exactitude, as opposed to the romanticism and mysticism which pervaded scientific thought in central Europe after the Napoleonic Wars. For 5 years while he was at medical school, Freud studied in the physiological laboratory of Ernst Brücke, a founder of the scientific movement known as the Helmholtz School of Medicine, which postulated that the only forces active in biological organisms were the physicochemical forces inherent in matter, "reducible to the force of attraction and repulsion." In a broader sense, according to the Helmholtz School, all biological organisms were phenomena of the physical world: systems of atoms, governed by forces, according to the principle of conservation of energy which had been described by Robert Mayer in 1842 and was applied by Helmholtz 20 years later. Freud was strongly influenced by these principles, and by Brücke, himself, who epitomized the qualities which he most admired, scientific discipline and intellectual integrity.

Medical career. Freud continued to work in Brücke's laboratory for a year after he graduated from medical school, and it was there that he developed the physiological framework into which he later tried to cast his psychological theories. Nor did Brücke's influence diminish throughout Freud's lifetime; his consistent, overriding goal was to apply to Brücke's principles to the study of the nervous system and then to the mind. As mentioned above, Freud made a number of attempts to do so before he became resigned to the fact that the lack of relevant physiological data precluded the explanation of mental phenomena in terms of the physicochemical nature of brain function. Although he never renounced Brücke's principles, thereafter he limited his theory of the mind

to the psychological parameters of mental functioning. Nevertheless, it would seem useful at this point to digress briefly to describe the essay entitled "Project for a Scientific Psychology," which represented Freud's most ambitious attempt to explain the physical roots of mental phenomena. Space limitations preclude a detailed outline of this remarkable document, which was written over a 2-year period from 1895 to 1897 and published posthumously. Its essential features may be summarized as follows.

Writing in the language of physics and brain physiology and drawing upon contemporary neurophysiology and neuroanatomical concepts, Freud attempted to conceptualize psychology as a natural science. To do this, he combined two theories. One, which may be attributed to the influence of the Brücke-Helmholtz School, stated that the laws which governed physics and chemistry were equally applicable to psychology. Secondly, the theory of neurones, which derived from Freud's neurohistological studies, was the basis for his attempt to describe the mind in terms of their neurones and their synapses.

According to the "Project," the functioning of the nervous system could be described in terms of two closely allied principles. The first principle, of "inertia," stated that neurones tend to discharge nervous excitation. Pain was related to excessive nervous excitation and pleasure to its discharge; this discharge of excitation was the primary function of the neuronic system. Its secondary function, which Freud explored in the "Project," concerned the choice of specific paths for the discharge of quantities of excitation which impinged upon the nervous system from the external world or from within the organism, in order to maintain psychic equilibrium. Secondly, Freud maintained that the functioning of the nervous system was governed by the principle of "constancy." This concept may be traced to the principle of the conservation of energy (Mayer and Helmholtz), which held that the sum of forces remains constant in every isolated system, and to Herbart's hypothesis that mental processes tend to strive for equilibrium (an idea which is similar to what Cannon later described as homeostasis). In 1892, Freud (with Breuer) defined constancy as follows: "The nervous system endeavors to keep constant something in the functional condition that may be described as the 'sum of excitation.'"

Despite the fact that many of the speculations advanced in the "Project" regarding the functioning of the nervous system were confirmed by subsequent neurophysiological investigations, clearly, the "Project" was premature in its effort to link mental and physiological phenomena. However, it did anticipate many of Freud's subsequent purely psychological concepts; for example, physiological principle of inertia was later translated into the psychoanalytic "pleasure-unpleasure" principle. But, most important, it demonstrated Freud's deep commitment to discovering a biological basis for his psychological theories.

To return to our chronological account of Freud's medical career, during the year he spent at Brücke's Institute, he did several highly creditable pieces of histological and neuroanatomical research. He found research particularly congenial, and he hoped to continue with his theoretical work. But financial considerations made this impossible. Despite a deep aversion to the practice of medicine as such, Freud was forced, by his personal economic situation, to leave the laboratory setting in 1882 and to begin work in the General Hospital in Vienna, first on the surgical service and then in Theodor Meynert's Psychiatric Clinic. As a student, only Meynert's medical lectures had aroused Freud's interest; and, while he was assigned to his service, he shared the general opinion that Meynert was the most gifted brain anatomist of his time. Freud was not quite so enthusiastic about Meynert's qualifications as a psychiatrist, however. He felt that the emphasis on neuroanatomy and neuropathology (which, in fact, was characteristic of psychiatry during this period) diminished Meynert's clinical competence. Nevertheless, as a result of his study of "Meynert's amentia" (acute hallucinatory psychosis), Freud obtained a vivid impression of the mechanism of wish fulfillment, which later became a basic part of his theory of the unconscious.

Interest in neurology. On Meynert's service, Freud increased his knowledge of brain disorders; concurrently, he received Meynert's permission to use his laboratory for an extensive study of the brain of the neonate. These events coincided with his decision to specialize in neurology, rather than engage in general practice, and, when he received a highly coveted traveling grant in 1885, he used it to go to Paris, where he studied at the Salpêtrière for 19 weeks under the great French neurologist, Jean-Martin Charcot. This was a crucial period in Freud's career. During the time he spent in Charcot's clinic, Freud was able to observe a wide variety of neurological syndromes. However, he was most impressed by Charcot's radical approach to hysteria. As a result of Charcot's influence, Freud became deeply interested in the problem of hysteria and firmly convinced that hysterical phenomena were genuine.

In fact, Charcot's teachings were in marked contrast to the view that had been prevalent up to that time, according to which hysterical phenomena were viewed either as deliberate pretense or as the product of the patient's "imagination," and, as such, were not to be taken seriously. As a result of Charcot's systematic and thorough study of the manifold manifestations typical of hysteria, it was recognized as a "legitimate" disease of the nervous system, and, as such, a possible subject of serious study and understanding.

The psychological explanation for hysterical phenomena was not investigated by Charcot. However, the possibility that such phenomena might be psychological in origin did occur to Freud when Charcot was able to precipitate hysterical paralyses, seizures, and

other characteristic symptoms artificially, through hypnotic suggestion. Thus, by means of his experiments in hypnosis, Charcot distinguished hysterical phenomena from organic neurological entities. Although he believed that hysteria had a neurological basis and, in fact, was due to congenital degeneration of the brain, the symptoms manifested in hysteria were psychogenic in origin; that is, they were produced by specific "ideas" held by the patient. And, by the same token, hysterical symptoms could be cured by "ideas."

The Austrian physician, Anton Mesmer, who died in 1815 at the age of 81, is generally credited with the discovery of hypnotism, which was to play such a crucial role in the development of psychoanalysis. Mesmer used the special power he called "animal magnetism" to "cure" people (often in dramatic public exhibitions) of afflictions which, in all probability, would be diagnosed today as hysterical symptoms. A century later, A. A. Liébault, a kindly French country doctor in Nancy, used hypnotic sleep to relieve countless peasants of their neurotic symptoms via the technique of suggestion. It remained for psychoanalysis to provide a rational scientific explanation of the psychological mechanisms operant in the psychoneuroses; however, psychotherapy, as a form of medical treatment, may be said to have had its beginning in Liébault's clinic. Freud was particularly interested in the work of Hippolyte Bernheim, an associate of Liébault, who used hypnosis as a therapeutic modality. On the basis of his careful study of the characteristics of suggestibility, Bernheim concluded that this phenomenon was not limited to hysterics. In fact, it was present in patients with a wide range of neurotic disorders and in normal individuals as well. Bernheim's attempt to account for a wide variety of normal and abnormal social reactions through suggestion or autosuggestion may well have represented the first attempt to understand human behavior and its motivation on the basis of data derived from clinical study.

Freud spent several weeks in Nancy during the summer of 1889. His visit was a profitable one, in several respects. He was deeply impressed by the relationship Liébault established with his patients and by the dramatic effects Bernheim was able to produce in his hospitalized patients through the use of hypnotic suggestion. Most important, as he observed Bernheim's experiments, Freud became profoundly aware of the possibility that powerful mental processes, which were hidden from consciousness, were operative in the minds of men.

In summary, then, Freud's approach to mental and emotional disorders and psychological phenomena up to this point can be traced to two principal influences. From the Helmholtz School, from his teachers, Brücke, Meynert, and Charcot, he had learned to emphasize rational scientific understanding, careful empirical

study, and clinical observation. From the French doctors, Liébault and Bernheim, he learned that the physician, himself, may play a useful role as an instrument of psychotherapeutic change. In addition, in the course of his visit to the Liébault Clinic, he gained the impression that deeper psychological forces, not immediately accessible to consciousness, were operative in human motivation and behavior. Initially, he was inclined to defend the orientation of the Helmholtz School, and of Brücke and Charcot in particular. Ultimately, his ability to integrate these diverse influences, together with the extraordinary psychological sensitivity and insight which characterized Freud's genius, enabled him to create a new science which represented a unique approach to the study and resolution of human conflict.

Freud returned to Vienna from Charcot's clinic in Paris in 1886 with the avowed intention of giving up his laboratory studies so that he might devote all his time to the clinical practice of neurology. Nevertheless, in 1891 he wrote a short book, entitled *Aphasia*, in which he challenged Wernicke's and Lichtheim's minute localization schemes of this disorder and instead offered a functional explanation which accounted for the subvarieties in terms of disruptions of the radiating associational pathways. Freud's work, which was the only one of the period to cite the genetic view of Hughlings Jackson, received little attention at the time; however, the validity of its basic principles has since been recognized. In 1891 and 1893, he published two exhaustive clinical studies of the paralyses of children. The first of these, written in collaboration with Dr. Oscar Rie, a pediatrician, dealt with the unilateral paralysis in children. It was widely acclaimed by neurologists, and even today it is considered a classic. The second presented an equally comprehensive study of the central diplegias in children.

Evolution of Psychoanalysis

Psychoanalysis as a method of investigation, a therapeutic technique, and a scientific discipline with a growing body of basic propositions and findings may be said to have evolved in the decade from 1887 to 1897, first through Freud's collaboration with Breuer, and then through his independent efforts.

Collaboration with Breuer. Even at the time the two works on childhood paralyses were written, however, Freud had already become deeply interested in clinical psychopathology. In part, this may be attributed to the fact that the cases seen by a neurologist in private practice were largely psychoneurotic rather than neurological. To an even greater extent, however, Freud's growing interest in psychopathology may be attributed to his association with Josef Breuer, a prominent Viennese physician, with whom he formed a close friendship while he was working at Brücke's Institute of Physiology. Breuer's treatment of the famous case of Frä. "Anna O." or, more specifically,

his communication to Freud of the details of that case, was one of the factors which led to the development of psychoanalysis. Breuer treated "Anna O." (Bertha Pappenheim) from December, 1880, to June, 1882. The patient was an intelligent girl of 21 who had developed a number of hysterical symptoms in association with the illness of her father, of whom she was passionately fond. These included paralysis of the limbs, contractures, anesthetics, disturbances of sight and speech, inability to take food, and a distressing nervous cough. Her illness was further characterized by two distinct phases of consciousness. During one, she was normal; during the second, she took on another personality. The transition between these states of consciousness was effected by autohypnosis, which Breuer subsequently supplemented with artificial hypnosis. Anna had shared with her mother the duties of nursing her father until his death. During her altered states of consciousness, she was able to relate the vivid fantasies and intense emotions she had experienced while tending her father. And to the great amazement of the patient—and Breuer—her symptoms could be made to disappear if she could recall, with an accompanying expression of affect, the scenes of circumstances under which they had arisen. Once she had become aware of the value of this "talking cure" or "chimney sweeping," Anna proceeded to "deal" with each of her manifold symptoms, one after another. For example, she recalled that on one occasion when her mother was absent and she had been sitting at her father's bedside, she had had a day-dream in which she imagined that a snake was coming to bite her sick father. When she tried to ward off the snake, her arm, which had "gone to sleep" over the back of a chair, seemed paralyzed. Moreover, the arm had remained paralyzed until the patient recalled the scene under hypnosis. Quite understandably, the case of Anna made a profound impression on Freud; it provided convincing evidence of the power of unconscious memories and suppressed affects in the production of hysterical symptoms.

Still another aspect of Breuer's treatment of Anna was of crucial significance for the future development of psychoanalysis: in the course of treatment, Breuer had become increasingly preoccupied with his unusual patient, and his wife had grown increasingly jealous and resentful. When he realized this, Breuer abruptly terminated treatment. Only a few hours had elapsed, however, before he was recalled to Anna's bedside. He found the patient, who he believed was greatly improved, in a state of acute excitement. Anna, who had never alluded to the forbidden topic of sex during the course of treatment was now experiencing a hysterical childbirth (pseudocyesis), the logical termination of the phantom pregnancy she had developed in response to Breuer's therapeutic efforts, of which he had been quite unaware. Breuer managed to calm her through hypnosis. However, the experience unnerved

him and served to restrict his further participation in Freud's investigations into the unknown (and therefore unpredictable and dangerous) sphere of the mind.

Independent investigations: Therapeutic technique

Use of hypnosis. Late in 1887, Freud began to use hypnosis intensively in his own practice. At first, he used hypnosis for the single purpose of getting the patient to deny the reality of his symptoms. It was evident, however, that even though the patient might deny his symptoms under hypnotic suggestion, he was well aware of their reality in waking life. Concomitantly, Freud found the contradiction and general superficiality of this approach a source of increasing dissatisfaction. Partly as a result of his interest in Breuer's treatment of "Anna O.," Freud was eager to learn what lay behind his patients' symptoms, to investigate them in depth, and it is this goal which continues to distinguish the more arduous psychoanalytically oriented treatment methods from those psychiatric treatment techniques which seek merely to suppress overt symptoms.

Accordingly, in 1889, Freud turned to the cathartic method (in conjunction with hypnosis) in order to retrace, as Breuer had in the case of Anna O., the history of the symptom. The first time he employed this method, in the case of Frau Emmy Von N., he adhered quite strictly to the concept of the traumatic origin of hysterical phenomena. Accordingly, the goal of treatment was limited to the removal of symptoms through recovery—and verbalization—of the suppressed feelings with which they were associated, a procedure which has since been described as *abreaction*. In his account of this case, Freud also hinted that inhibited sexuality may have played a role in the etiology of the patient's symptoms.

Once again, however, he was dissatisfied with the results he achieved. The beneficial effects of this hypnotic treatment were transitory; they lasted only as long as the patient remained in contact with the physician. Freud suspected, therefore, that they were, in fact, dependent upon the personal relationship between patient and physician. Freud's suspicion was confirmed when, one day, a patient awoke from a hypnotic sleep and suddenly threw her arms around his neck. Breuer had told him earlier of the events which followed the termination of his treatment of Anna O. Now Freud himself had an opportunity to observe a similar reaction in a patient he had been treating. Fortunately, unlike Breuer, he was not frightened by this experience. Rather, it aroused his scientific interest.

More specifically, from this point on, Freud understood that the therapeutic effectiveness of the patient-physician relationship, which had so mystified him, could be attributed to its erotic basis. (Many years later, he said that he had also regarded these trans-

ference phenomena as definitive proof of the sexual etiology of the neuroses.) In any event, these experiences served to underscore his dissatisfaction with hypnosis. At a later stage in the development of psychoanalysis, Freud described hypnosis as a "mask" which concealed, and therefore precluded, investigation of the transference and resistance phenomena which are central to psychoanalytic theory and practice. In essence, his decision to make the crucial transition from Breuer's cathartic method to another more suitable technique was based on similar, albeit less sophisticated considerations. He wanted to be "free" of hypnosis because it had become increasingly apparent that the hypnotic method owed its success to the fact that the patient acted out of love for her doctor. That is, she remembered traumatic experiences and feelings at his command and, concomitantly, appeared to recover from her illness, in order to please him. Obviously, a cure which did not involve some understanding on the part of the patient of the origins and significance of her symptoms could only be temporary, at best. Freud's decision was based on other considerations as well: he had found that many of the patients he encountered in private practice were refractory to hypnosis. Later, he recognized that his inability to hypnotize a patient might be due to the patient's reluctance to remember, and he identified this as resistance. At the time, however, he was eager to develop a treatment method which might be applied whether or not the patient was "hypnotizable." Freud continued to use hypnosis, where indicated, until he had refined the technique of free association to his entire satisfaction. He reached this point in 1896, and he never used hypnosis again.

"Concentration" method. In 1892, Freud undertook the treatment of Frl. Elisabeth von R., a patient whom he had earlier found to be refractory to hypnosis, and for the first time abandoned this therapeutic tool. His decision to make this attempt was based largely on a statement made by Bernheim to the effect that although they appeared to be forgotten afterward, the experiences recalled under hypnosis could once again be recalled in states of consciousness, if the physician asked the patient leading questions and urged him to produce these crucial memories. (Concentration was based on this premise. The patient was asked to lie down on a couch and close her eyes. She was then instructed to concentrate upon a particular symptom and to try to recall memories. Concurrently, Freud pressed his hand on her forehead in order to facilitate the emergence of such memories, even as he urged her to remember and continued to question her.)

Free association method. The use of free association as a therapeutic technique evolved very gradually from these beginnings over the 3-year period from 1892 to 1895. The first step in its development came about when the patient, Elisabeth von R., remarked that she had not expressed her thoughts because she

wasn't sure what Freud wanted to hear. From this point on, Freud no longer tried to direct the patient's thinking but encouraged her to ignore all censorship and to express every idea that occurred to her, no matter how insignificant, irrelevant, or shameful it might seem. Again, at a later point in treatment, the patient complained that Freud had interrupted her train of thought by his persistent questions and that she found his habit of pressing his hand on her forehead an unnecessary distraction.

In brief, by the late 1890's, both Freud and his patients had come to feel that the urging, pressing, and questioning which were part of the "concentration" method actually interfered with the free flow of thought. Accordingly, these procedures were abandoned, and eventually patients were no longer instructed to close their eyes. However, the use of the couch continues to play a central role in classical psychoanalysis, and the fundamental rule of the free association method has remained unchanged.

Theoretical contributions

Etiological propositions. The application of free association as a treatment method served to illuminate aspects of mental functioning which had never been observed previously. For one, Freud discovered that a patient's train of memory extended well beyond the traumatic event which had precipitated the onset of his illness. Rather, he found that his patients were able to produce memories of their childhood experiences, of scenes and events which they thought had long been forgotten. This discovery led, in turn, to the conclusion that, frequently, these memories had been inhibited previously because they involved sexual experiences or painful incidents in a patient's life. Moreover, he learned that the recollection of such experiences even in the present could evoke intense excitement, moral conflict, feelings of self-reproach, or fear of punishment. Since these childhood experiences remained so vivid, obviously they must exert a "predisposing" influence in relation to the development of psychoneurosis. Inevitably, this led to extensive modification in the view prevalent at the time and shared by Freud, that heredity must be accorded a major role in the predisposition to neurosis. Freud continued to acknowledge the role of heredity in determining an individual's future susceptibility to neurosis, an opinion which most psychoanalysts share today. However, he assigned much of the responsibility for the etiology of the psychoneuroses, which had hitherto been attributed to heredity, to unfavorable childhood experiences. He further postulated that hysteria might be acquired, as well as congenital. Emotionally disturbing experiences played a major role in the etiology of "acquired hysteria," while hereditary factors were of minor importance.

Concept of resistance. As mentioned above, Freud discovered early in his practice that his patients were

often unwilling or unable to recount memories which later proved to be etiologically significant. He defined this reluctance, as it manifested itself in the treatment setting, as resistance. However, his initial observations were supplemented later by data derived from his clinical investigations. He found that, in the majority of patients he treated, resistance could not be attributed to a reluctance to cooperate (i.e., to obey the rule of free association). Nor were they unwilling to get well, for frequently those patients who were most distressed and embarrassed by their illness were most hampered in treatment by this phenomenon. Rather, resistance was due to active forces in the mind, of which the patients themselves were often unaware, which led to the exclusion from consciousness of painful or distressing material. Freud described this active force as repression, and this concept remains one of the cornerstones of psychoanalytic theory.

Repression. In a broad sense, Freud considered repression to be at the core of symptom formation. He described the mechanism as follows. A traumatic experience or series of experiences, usually of a sexual nature, which had occurred in childhood, had been "forgotten" or, more accurately, repressed because of their painful nature. However, the excitement associated with the event has not been extinguished, and its traces persist in the unconscious in the form of repressed memories. These memories remain without pathogenic effect until some contemporary event, such as a disturbing love affair, revives them. At this point, there is a breakdown of the successful repression and what Freud termed "the return of the repressed"; this signals the onset of the period of illness proper. The original sexual excitement is revived and is now forced to find a new path or outlet. The clinical manifestation or symptom results from a compromise between the repressed desire and what Freud called the "dominant mass of ideas constituting the ego."

Cases of conversion hysteria were considered of particular relevance in this connection and were studied carefully by Freud during the 1890's. More specifically, in such cases impulses which were not allowed access to consciousness followed the path of somatic innervation, resulting in such symptoms as paralysis, blindness, disturbances of sensation, and less disguised hysterical attacks. However, despite his emphasis on conversion hysteria as the prototype of repression, Freud believed that the basic proposition, i.e., that symptoms resulted from a compromise between a repressed impulse and the repressing forces in the personality, applied to obsessive-compulsive phenomena as well, and even to paranoid ideation. As a logical consequence of this hypothesis, psychoanalytic treatment during this period consisted of helping the patient to recall repressed sexual experiences so that the excitation which had accompanied such experiences could find its way to consciousness and be discharged through verbalization with accompanying remembered affect.

Theory of infantile sexuality. One final, yet fundamental, modification of these early ideas had still to be made before psychoanalysis could come into its own as a "depth psychology" which presented a new science of the human mind. During the middle 1890's, Freud's clinical experience had led him to devote increasing attention to the importance of sexual seduction in the etiology of the psychoneuroses, especially when such seduction had occurred prior to puberty. He had even distinguished obsessional neurosis from hysteria on the grounds that in the former the subject actively and aggressively pursued the precocious sexual experience, while in hysteria the subject remained passive during the trauma. The important point was that until this time he had taken literally his patients' "tales of outrage" committed by their fathers, nursemaids, etc., but had devoted little attention to the role of the child's own psychological life in the elaboration of these tales. The specific factor which precipitated a radical change in this view has not been clearly delineated. There are several possibilities, however. For one, he had gained additional insight as a result of his clinical investigations of the role of fantasy in childhood. Secondly, his own self-analysis had clearly demonstrated the child's inclination to distort reality to conform with his wishes. There is a third possibility that he simply began to doubt there could be so many wicked fathers in middle class Vienna. In any event, in a letter to his friend, Wilhelm Fliess, in September, 1897, he expressed his doubts as to the veracity of his patients' reports of seduction and suggested instead that "sexual phantasy regularly makes use of the theme of the parents."

At first, the obvious validity of this new insight seemed to threaten the very foundation on which his theories rested, but his depression did not last. He sensed that this discovery offered new possibilities for the study of psychological factors. In attempting to distinguish psychic reality and fantasy from actual events, and psychoneurosis from perversion, psychoanalysis had taken on a new dimension. A dynamic theory of infantile sexuality, in which the child's own psychosexual life played a dominant role, could eventually replace the static concepts in which the child represented an innocent whose eroticism was prematurely and consistently disrupted at the hands of unscrupulous adults. Writing to Fliess, he recalled a quote from a story which was applicable to these new developments in psychoanalysis: "Rebecca, you can take off your wedding-gown, you're not a bride any longer. . . . In the general collapse only the psychology has retained its value." In fact, however, for psychoanalysis there would never be a honeymoon. After an initial period of rejection by the medical world, it entered a period during which it assumed its full responsibilities as a psychological science. The fact that Freud himself turned to the study of dreams, to his self-analysis, to his theory of the mind, to further studies of infantile sexuality, and to the origins and

nature of the psychoneuroses, was additional evidence of its maturation. It was the end of the beginning.

Summary: Therapeutic and theoretical contributions (1887–1897). By 1897, the fundamental concepts of psychic determinism and the operation of a dynamic unconscious were established, and, concomitantly, a theory of psychoneurosis based upon psychic conflict and the repression of the memories of disturbing childhood experiences was clearly outlined. Sexuality, especially in early childhood, was revealed to play an important role in the production of psychological symptoms that had not been recognized hitherto. Above all, a technique, a method of investigation had been developed that could be used to explore a wide range of mental phenomena which had been poorly understood before Freud's time. Nor were the applications of psychoanalysis restricted to the systematic study of psychopathological conditions; it provided an approach to the understanding of dreams, creativity, wit, and other normal mental phenomena as well.

Framework of Psychoanalytic Theory: The Theory of the Instincts and the Psychic Apparatus

Throughout his lifetime, Freud's thinking was characterized by a tendency to describe various aspects of mental functioning as successive series of contrasting phenomena. Moreover, he suggested that mental life, in general, was dominated by three polarities: the first, subject (ego) versus object (outer world), represented the polarity of reality; the second, pleasure versus unpleasure, was designated as an economic polarity; and the third, activity versus passivity, was identified as a biological polarity. In fact, this dualistic view reflects the essential nature of the instrument studied, the human mind. Yet it is possible that we are straitjacketed by this view in our attempt to understand the mind; in that event, a strict adherence to the dualistic approach should be seriously questioned. Psychoanalytic theory is founded upon dualisms to so great an extent, however, that it cannot be discussed accurately without thinking in such terms, and this discussion will not be an exception. Nevertheless, the possibility that a dualistic approach might provide a distorted view of the phenomena under consideration should be taken into account.

Basically, the body of psychoanalytic theory may be divided into the theory of the instincts or drives, on the one hand, and the psychic apparatus as it deals with these instincts, on the other. This part of the section is concerned with that part of the psychoanalytic theory which deals with the development of the sexual and aggressive instincts, in terms of their source, aim, impetus, and object, and with related phenomena. The next part of the section will focus on the formation and function of the psychic apparatus, or what is currently known as ego psychology.

More specifically, all human beings have similar instincts. The actual discharge of instinctual impulses

is organized, directed, or, if necessary, suppressed by the individual ego, which serves as the mediator between the organism and the external world. Historically and logically, the detailed attention to the instincts in psychoanalysis preceded the preoccupation with ego psychology. Obviously, one would not attempt to investigate an apparatus whose function it is to organize, direct, and suppress, without prior understanding of the precise nature of the phenomena which were organized, directed, and suppressed. However, to an increasing extent, the study of the ego as a product of the interplay of unconscious instinctual demands and environmental influences has become a dominant concern of psychoanalysts and behavioral scientists in allied disciplines, to the degree that several workers feel that there has been a concomitant deemphasis on the study of the deeper forces of the mind. The question is open to argument.

With specific reference to this presentation, no attempt has been made to order the discussion of these concepts on the basis of their importance. Nor will it be possible to discuss these concepts in strict chronological sequence, although their historical evolution will be indicated where this is possible. Finally, certain areas of psychoanalytic study, such as anxiety, symptom formation, the phenomenon of narcissism, the theory of the mind, and character development, may be discussed appropriately from two vantage points: In this part of the section these phenomena will be discussed in relation to the formation of the basic—and universal—instincts and drives. The following part of the section will focus on their relationship to the structure and function of the psychic apparatus, which permits psychoanalysis to understand individual differences among human beings from a causal and genetic point of view.

Development of the Instincts

Libido theory. There is some confusion as to what Freud meant by the term "libido." In brief, Freud regarded the sexual instinct as a psychophysiological process (as did everyone else), which, therefore, had both mental and physical manifestations. Essentially, he used the term "libido" to refer to "that force by which the sexual instinct is represented in the mind," and it is used here in this accepted sense, i.e., as referring specifically to the mental manifestations of the sexual instinct.

As mentioned earlier, Freud recognized that the sexual instinct did not originate in finished form (i.e., as represented by the stage of genital primacy). Rather, it underwent a complex process of development, during which it had many manifestations apart from the simple aim of genital union. The libido theory referred to the investigation of all of these manifestations and the complicated paths they might follow in the course of development.

Infantile sexuality. Of all of Freud's theories, the concepts he advanced with regard to the erotic life of

infants and young children undoubtedly aroused the most violent and continued opposition. Indeed, even today, many "sophisticated" psychiatric residents react with complete incredulity to the elucidation of sexual material in a clinical demonstration of a case of childhood neurosis. Freud's theory of infantile sexuality threatened to undermine one of the most cherished ideals of the 19th century, the innocence of children. Moreover, the belief that children, and especially infants, are somehow "above" sexual longings persists today; nor is this belief confined to the uneducated. Under the circumstances, the theory of infantile sexuality is certainly an outstanding example of the courage Freud demonstrated in his pursuit of scientific truth in the face of the most adverse public opinion.

Freud had become convinced of the relationship between sexual traumata experienced in childhood and later psychopathology as a result of his early investigations of the "actual neuroses" (i.e., hypochondriasis, neurasthenia, and anxiety neurosis). And these studies had, in turn, led to awareness of the importance of sexual factors in the etiology of the psychoneuroses. With increased clinical experience, Freud was able to reconstruct the early sexual experiences, responses, and fantasies of his patients. These data provided the framework for a developmental theory of childhood sexuality, which in the years since has been corroborated in many respects by direct observation. Apart from the data he had extracted from his clinical experience, Freud based his theory on the self-analysis he began in 1897 and continued for an undetermined period. The insights he acquired in the course of the analysis regarding his own erotic longings in childhood and his conflicts in relation to his parents clearly suggested that, in all likelihood, these phenomena were not restricted to the neuroses, that "normal" individuals underwent similar developmental sequences.

Freud had completed his formulations concerning all the essential phases of sexual development before the turn of the century. Nevertheless, *Three Essays on the Theory of Sexuality*, containing a full account of his startling views, was not published until 1905. Even more surprising is the fact that his detailed discussion of the sexual development of children (including the pregenital organization of the libido) and the libido theory itself appeared for the first time in the third edition of the *Three Essays*, 10 years later.

In essence, while Freud used the term sexuality in these essays in the familiar sense, to refer to the erotic life of the individual, he extended the general concept concerning those sensations and activities which are typically considered "sexual," and those parts of the body which are usually associated with eroticism. Freud noted that infants were capable of erotic activity from birth, and he described the various stages of sexual development during the first 4 years of life. The 5th year marks the beginning of the "latency

period," at which point sexual development comes to a halt (although this will depend on the individual) until the child reaches puberty when he is approximately 11 years old. At puberty there is renewed growth of the genital organs and a resurgence of the sexual drive, and the child begins his final preparations for the adult sexual role.

Phases of psychosexual development. The earliest manifestations of sexuality arise in relation to bodily functions which are basically nonsexual, such as feeding and the development of bowel and bladder control.

The oral phase. Erotic activity during this phase, which extends into the 2nd year of life, centers on the mouth and lips and is manifested in sucking, biting, and chewing.

The anal phase. As a concomitant of the child's increasing preoccupation with bowel function and control, the dominant erotic activity then shifts from the oral to the anal and rectal regions, from ages 2 to 4.

The genital or phallic phase. The genital phase of sexual development begins some time during the 3rd year of life and continues until approximately the end of the 5th year. Initially, erotic activity is linked both psychologically and physiologically with the activities and sensations associated with urination. However, Freud postulated that in boys phallic erotic activity was essentially a preliminary stage for adult genital activity. On the other hand, in contrast to the male, for whom the principal sex organ remains the same throughout, the female has two leading erotogenic zones—the clitoris and the vagina. The clitoris is preeminent during the infantile genital period of development. However, development is complicated by the fact that during or after puberty the transition must be made to vaginal primacy.

Karl Abraham, one of the most gifted psychoanalytic pioneers whose premature death was considered a great loss to psychoanalysis, further subdivided these phases of libido development. He divided the oral period into a sucking and biting phase, and the anal phase into destructive-expulsive and mastering-retaining phases. Finally, he hypothesized that the phallic period comprised an early phase of partial love, which was designated as the true phallic phase and a later, more mature genital phase.

Freud suggested, in connection with this elucidation of sexual development, that there were three phases of genital masturbatory activity: during early infancy, at the highest point of infantile sexuality, and during puberty. During the earliest months of life the genital region may be stimulated (in both boys and girls) inadvertently by the mother. However, masturbatory activity (i.e., stimulation of the penis in boys and the clitoris in girls) reaches its peak some time during the 3rd year of life and continues until the end of the 5th year.

As indicated earlier, for each of the phases of psy-

chosexual development described above, Freud delineated specific erotogenic zones, that is, various regions of the body which might be the source of erotic sensation.

Vicissitudes of infantile sexuality

The part instincts. During infancy and early childhood, for the most part, erotic sensation emanates from the mucosal surfaces of a particular body part or organ. More specifically, during the earliest years of life, the mucous membranes of the mouth, anus, or external genitalia are the appropriate primary focus of the child's erotic life, depending on his or her phase of development. Subsequently, in normal adult sexual activity, the genital zone becomes predominant. However, the pregenital or prephallic erotogeneity of the oral and anal zones still retains a place in preliminary mating activities, i.e., in the "foreplay" or "fore-pleasure" which precedes coitus, which, ideally, culminates in "end pleasure," i.e., orgasm.

Freud described the erotic impulses which arise from the pregenital zones as component or part instincts. Kissing, stimulation of the area surrounding the anus, or biting the love object in the course of lovemaking would be examples of activities associated with these part instincts. Early genital excitement may undergo displacement to the eyes, for example, and looking and being looked at (scotophilia) may be a source of pleasure. Ordinarily, in the course of development, these component instincts undergo repression or retain a restricted role in sexual foreplay. More specifically, normally, the young child is characterized by polymorphous perverse sexual instincts; that is, his total sexuality is undifferentiated and encompasses all of the part instincts. However, as mentioned above, in the adult these part instincts are expected to become subordinate to the primacy of the genital region. The failure to achieve genital primacy may result in various forms of pathology. If, for example, the libido becomes too firmly attached to one of the pregenital erotogenic zones, or a single part instinct is predominant, a "perversion," such as fellatio or voyeurism, which ordinarily would be limited to the preliminary (preparatory) stages of lovemaking, would replace the normal act of sexual intercourse. The persistent attachment of the sexual instinct at a particular phase of pregenital development was termed a "fixation."

Neurosis and perversion. Freud further discovered that in the psychoneuroses only a limited number of the sexual impulses which had undergone repression and were responsible for creating and maintaining the neurotic symptoms were of a "normal kind." For the most part, these were the same impulses which, in the perversions, were given overt expression. The neuroses, then, were the "negative" of perversions. However, the relationship between psychoneuroses and perversions is not nearly so simple as it might seem at first glance. Its more complex aspects

are elaborated on in detail below. For example, at this point in its development, Freud's theory could not account for the fact that in one case a part instinct might be repressed and contribute to neurotic symptom formation, while in another case the part instinct retained overt dominance over the individual's sexual activity in the form of a perversion. In other words, although the theory of sexuality encompassed the concept of fixation of the libido, insofar as it was limited to the description of various potential zones of libidinal stimulation and excitement, it was unable to explain the outcome of fixation in a particular case. The resolution of the problem had to await the development of later theories concerning the defense mechanisms, the functions of the ego and the superego, and the nature and role of anxiety in mental functioning.

Social and cultural implications of the theory of infantile sexuality. Despite the anger and general sense of outrage they evoked initially, Freud's investigations of the sexual development in early childhood had important social and cultural consequences. For one, they have given rise to a more enlightened approach to the child's sexual explorations and a more respectful attitude toward his expressions of sexual curiosity. Moreover, in general, our greater sexual freedom and the development of a more rational morality can be attributed to Freud's discoveries. Under the circumstances, it is rather ironic to realize that even today Freud's theory of infantile sexuality evokes strong resistance. (Indeed, it is even more ironic that such resistance should persist among professionals and laymen alike, in view of Freud's elucidation of its origins and nature as a concomitant of his investigations in this area.) Nevertheless, apparently his vivid case histories did successfully demonstrate the possible repercussions of undue sexual restrictions and harshness, especially in the critical stages of development. As a result, he was able to influence the sexual attitudes of successive generations, even where there was no real acceptance of the theoretic principles involved.

Development of object relationships. Current theories in psychoanalytic psychiatry have focused increasingly on the importance for later psychopathology of disturbances in early object relationships (i.e., the relationship of affect to an object outside one's self). And, concomitantly, those workers who emphasize the importance of "cultural" factors in development have criticized Freud for setting forth a timetable of infantile sexual development in a "social vacuum" without taking into account the impact on the child of the adults with whom he comes into contact. In fact, however, the criticism which has been leveled against Freud on this score is patently unjust. Even the most cursory examination will disclose that Freud's early writings on sexual development incorporated his basic concepts of object relationships as they evolved in relation to the sexual instinct, and

that he considered these phenomena closely interwoven. Nor is this surprising when one considers that the libido theory evolved from the crucial insight Freud acquired early in his clinical experience that the sexual fantasies of his adult patients typically centered on their early relationships with their parents. In any event, throughout his descriptions of the libidinal phases of development, Freud made constant reference to the significance of the child's relationships with crucial figures in his environment. More specifically, he postulated that the choice of a love object in later life, the love relationship itself, and object relationships in other spheres of activity would depend largely on the nature and quality of the child's object relationships during the earliest years of life.

Object relationships during the pregenital phases of development. At birth, the infant has no awareness of the external world of objects. At most, he is capable of an undifferentiated sensitivity to pain and pleasure. More precisely, hunger, cold, and pain give rise to tension and to a corresponding need to seek relief from these painful stimuli in sleep. At the same time, the human infant is more helpless than other mammals, and his helplessness continues for a longer period of time. He cannot survive unless he is cared for, and he cannot achieve relief from painful stimuli without help from outside. Object relationships of a primitive kind are established when the infant begins to grasp this fact. Because he is aware only of his own tension and relaxation and unaware of the external world, longing for the object exists only as long as disturbing stimuli persist and the object is absent. Once the object appears and the infant's needs are gratified, the longing disappears.

The oral phase. The infant's first awareness of an object, in a psychological sense, comes from his longing for something which is already familiar, for something which gratified his needs in the past but is not immediately available. Essentially, it is hunger which compels the infant to recognize the outside world. In this context, the infant's primitive reaction to the first objects, i.e., his desire to put them in his mouth, becomes understandable. Moreover, this reaction coincides with his first recognition of reality: the infant judges reality in terms of whether something will provide satisfaction (and should, therefore, be swallowed), or whether it will create tension (and, consequently, it should be spit out).

It is at this point that the mother becomes more than an anonymous agent, whose ministrations keep the infant alive. She is recognized as the source of nourishment and, beyond this, as the source of the erotogenic pleasure the infant derives from sucking. As such, she becomes the first love object. From the oral phase onward, sexual development, that is, the focus on successive erotogenic zones and the emergence of associated component instincts, will reflect the child's attachment to the crucial people in his environment and his feelings of love or hate (or an ad-

mixture of both) toward these important persons. For example, if a fundamentally warm relationship between mother and child has been established during this period, theoretically at least the stage will be set for the development of trusting and affectionate ties to others in later life.

At first glance, this "formula for success" would appear to be relatively simple and clear cut. However, in fact, the oral stage is not without its possible perils in terms of the course of future development. Apart from the adverse consequences which are typically associated with the mother's rejection or undue frustration of the infant's needs, distortions in the early mother-child relationship may have more subtle, but equally severe repercussions. As mentioned earlier, Abraham subdivided the oral stage into a sucking and biting phase. Inevitably, the frustration associated with the latter part of the oral period, and particularly with the weaning process, which, to the child, signifies the imminent loss of oral gratification, evokes biting and cannibalistic impulses toward the object. When such impulses are excessive, they may be a prelude to later serious impairment of object relations.

The anal-sadistic phase. In a broad sense, the infant's role during the oral phase of development is a passive one. That is, the onus is on the mother to gratify (or frustrate) his demands. In contrast, during the anal period, the child is expected, for the first time, to relinquish one aspect of his freedom: he is expected to accede to his mother's demand that he use the toilet for the evacuation of feces and urine. The primary aim of anal eroticism is the enjoyment of the pleasurable sensation of excretion. Later on, the stimulation of the anal mucosa through retention of the fecal mass may be a source of more intense pleasure.

The connection between anal and sadistic drives may be attributed to two factors. First, the object of the first anal-sadistic activity is the feces themselves, and their "pinching off" is perceived as a sadistic act. Subsequently, people are treated as feces were previously. The sense of social power which evolves from sphincter control constitutes the second sadistic element: in training for cleanliness, the child exerts his power over his mother by giving up, or refusing to give up his feces.

The first anal strivings are autoerotic. Pleasurable elimination (and at a later point, pleasurable retention) does not require the outside help of an object. At this stage of development, defecation is invested with omnipotence, and the feces, which represent the agent of such pleasure, become a libidinal object, so to speak, by virtue of their narcissistic evaluation. Although they have become external, they have "ego quality," for they represent part of what was once one's own body. Hence, there is a tendency to reintroduce what was once eliminated, in order to restore narcissistic equilibrium. Thus, the feces become an ambivalently loved object: They are loved and retained

or reintrojected, on the one hand; and they are hated and "pinched off" on the other.

Certain pleasurable anal sensations are associated with the mother's ministrations (e.g., diaper changes). This maternal care, in combination with the conflicts which surround toilet training, subsequently alters the direction of object strivings. However, as mentioned above, people are treated in much the same way feces were earlier. The compulsive neatness which is typical of patients who have regressed to this pre-genital phase of development is an expression of their wish to dominate. They exert power over things and people and force them into a rigid and pedantic system. Concomitantly, their feelings are characterized by the ambivalence referred to earlier, i.e., the tendency to control and retain the object, together with a desire to expel and destroy it.

The connection between anal eroticism and the physiological basis for ambivalence derives from the fact that during this stage in his development the child treats the object, i.e., feces, in a contradictory manner. He alternately expels the matter from his body and retains it as a loved object.

Finally, Abraham considered his subdivision of the anal-sadistic stage cited earlier of crucial importance, for at the dividing line between these two phases a decisive change occurs in the individual's attitude toward the external world. It is at this point that the tendency to preserve the object becomes preeminent and the capacity for object love begins (albeit in a restricted sense).

The phallic or genital phase: The Oedipus complex. Although some progress is made toward finding a love object during the pregenital phases of development, for the most part, the child's libidinal activity is autoerotic; that is, sexual impulses are directed toward his own body and discharged through masturbatory activity. The fundamental task of finding a love object belongs to the phallic or genital period, at which time the pattern for later object choices is set down; for now the child discovers the anatomical differences between the sexes. The events associated with this genital phase set the stage for the developmental predisposition to later psychoneuroses. Freud used the term "Oedipus complex" to refer to the intense love relationships which are formed during this period, together with their associated rivalries, hostilities, and emerging identifications. More precisely, the Oedipus complex represents the climax of infantile sexuality. The transition from oral eroticism via anal eroticism toward genitality, and the various associated stages in the development of object relations, culminate in oedipal strivings. An overcoming of these strivings, which are then replaced by adult sexuality, is a prerequisite for normal development; conversely, the neuroses are characterized by an unconscious clinging to oedipal tendencies.

The Oedipus complex evolves during the 3rd to the 5th years in children of both sexes. However, there is

some discrepancy in the development. Freud explained the nature of this discrepancy as follows. In boys, under normal circumstances, the Oedipus complex is resolved by the castration complex; that is, oedipal strivings are given up because of castration anxiety. In contrast, in girls, the Oedipus complex is evoked by the castration complex; more specifically, the girl turns to her father out of disappointment over the lack of a penis.

The castration complex. In boys, the development of object relationships is relatively simple because the boy remains bound to his first object, the mother. Moreover, the primitive object choice which first develops in response to the mother's fulfillment of the infant's basic needs takes the same direction as that which arises later in response to the attraction of the opposite sex. Thus, in the phallic period, in addition to the child's interest in the mother as the source of nourishment, he develops a strong erotic interest in her, and a concomitant desire to possess her exclusively. These feelings usually become manifest at the age of 3 and reach a climax in the 4th or 5th year of life.

With the initial appearance of the Oedipus complex in the phallic phase of development, the boy begins to "court" his mother almost as a lover would, expressing his wish to sleep in her bed, proposing marriage, and taking advantage of any opportunity to watch her dress or undress. Competition from his siblings for the mother's affection is, of course, intolerable. But, above all, he wants to eliminate his arch rival—her husband and his father. The child anticipates retaliation for his aggressive wishes toward his father, and these in turn give rise to severe anxiety. More specifically, he begins to feel that if he continues to show sexual interest in his mother, his penis will be removed. The idea of such deprivation in association with the male organ was identified by Freud as the "castration complex." In "The Passing of the Oedipus Complex," Freud further suggested that in the phallic period, the narcissistic fear about the penis is, in fact, stronger than the object relationship (i.e., the erotic attachment to the mother). Gratification of the boy's passionate love for his mother would endanger his penis. Confronted by the threat of castration, especially from his father, and the anxiety it evokes, the boy must finally "renounce" his oedipal love for his mother. And now he identifies with his father and incorporates within himself his father's prohibitions. In so doing, he manages to internalize, to "cover up" the castration complex, and it also remains free from external authority until it is reactivated at puberty.

The boy's love for his mother remains the dominant striving during this period of infantile sexual development. However, love and competition are not mutually exclusive: the boy loves his father too, and, at times, when he has been frustrated by his mother, he may hate her, or he may love both parents at the same time. In fact, the situation becomes even more complex in

the light of the psychoanalytic hypothesis concerning the bisexual nature of the libido. Thus, on the one hand, the boy wants to possess his mother and kill the hated father-rival; and, on the other hand, he loves his father and reacts to his mother with hostility when her demands on her husband interfere with the exclusiveness of the father-son relationship. The "negative Oedipus complex" refers to those situations where the boy's love for his father is prevalent, and the mother is hated as a disturbing element in this love. Obviously, under certain circumstances the reversal of the typical oedipal triangle may have serious implications for future development. It must be emphasized, however, that the negative Oedipus complex is normally present, to some degree, along with its positive, familiar orientation. The point is that under normal conditions, these conflicting feelings are able to coexist for a temporary period without provoking undue conflict.

The girl's situation. Understanding of the little girl's more complex oedipal situation came later, for it raised a number of questions which proved more difficult of solution. Despite the validity of Freud's basic propositions in this area, the further elaboration and clarification of his concepts had to await the researches of his able female colleagues, notably, Helene Deutsch, Ruth Mack Brunswick, and Jeanne Lampl-de Groot.

As in the boy's case, the little girl forms an initial attachment to her mother, as the source of fulfillment of her vital needs. However, unlike the boy, for whom the mother remains the love object throughout, the girl is faced with the task of shifting this primary attachment from the mother to the father in order to prepare herself for her future sexual role. Thus, essentially, Freud was concerned first with elucidating the factors which influence the little girl to give up her pre-oedipal attachment to the mother and form the normal oedipal attitude toward the father. Secondly, he was preoccupied with the factors which led to the dissolution of the Oedipus complex, in the girl, so that it might be replaced by adult sexuality.

The girl's renunciation of the pre-oedipal attachment to the mother could not be satisfactorily explained as a consequence of the ambivalent or aggressive qualities which characterize the mother-child relationship at certain phases of development, for boys participate in the same type of relationship. Rather, the crucial precipitating factor was found to lie in the anatomical differences between the sexes, or, more specifically, the girl's discovery of these differences during the phallic period. Until this discovery, apart from constitutional differences, and depending on the extent to which these are accentuated by variations in the parents' early attitudes toward a daughter, in comparison with a son, the girl's development parallels that of the boy. Fundamental differences emerge when she discovers, during the phallic period, that the clitoris with which she is endowed is inferior to its

male counterpart, the penis. Typically, the little girl reacts to this discovery with an intense sense of loss and injury and with envy of the male. And at this point, the mother, who had previously been an object of love, is held responsible for bringing her into the world less well equipped and engenders hostility so intense that it may persist. With the further discovery that the mother lacks this vital organ as well, her devaluation becomes even more profound. In an attempt to make up for her "inadequacy," the little girl turns to her father, in the hope that he will give her a penis, or a baby in place of the missing penis. The factors which lead to the dissolution of the Oedipus complex in girls, Freud's second concern, now appeared to be the following: the diminution of the girl's sexual love for her father because of his failure to satisfy her demands, and fear of the mother's disapproval.

Significance of the Oedipus complex. As mentioned earlier, Freud regarded the Oedipus complex as the nucleus for the development of later neurosis and symptom formation. Furthermore, the various admixtures of libidinal fixations, object orientations, and identifications with which the child emerges from the Oedipus situation exert a profound influence on the development of character and personality. This is a current concern of psychoanalytically oriented psychiatry. As such, the processes which enable the resolution of the Oedipus complex as the child emerges into the latency period clearly merit more detailed discussion than has been provided here. These processes are so intimately bound up with the development of the psychic apparatus and its structural components that it was considered appropriate to defer this discussion for presentation in the following part of the section, which is devoted to these areas of psychoanalytic theory. However, it should be emphasized here, once again, that in puberty there is a resurgence of incestuous oedipal feelings in both sexes, and the task of withdrawing libido from the parents and attaching it to other, more suitable love objects becomes of critical importance. Finally, with parenthood, the father and mother each reexperiences his early relationship with his own parents through identification with his child.

The nature and origins of anxiety

Initial formulations. Freud's first theory of anxiety emphasized its biological genesis in the sexual instinct. Thus, as a result of his early clinical studies in the 1890's, pathological anxiety was uniformly attributed to disturbance in sexual function. However, Freud distinguished between the etiological factors which produce anxiety in specific clinical entities. On the one hand, in those syndromes which he classified as the "actual neuroses" (i.e., neurasthenia, hypochondriasis, and anxiety neurosis), the causative factors have a physical basis. In contrast, he attributed the psychoneuroses, such as hysteria, primarily to psychological factors.

According to Freud, an increase in sexual tension (as a physiological phenomenon), leads to an increase in its mental representation, i.e., libido, together with various associated ideas and emotions. In the normal course of events, this sexual tension is discharged somatically through sexual intercourse, and, concurrently, its mental representations as well. However, in the actual neuroses, such as anxiety neurosis, abnormal sexual practices, i.e., coitus interruptus, prevent the proper somatic discharge of sexual tensions or "toxins" and, concomitantly, the adequate expression of the psychic elaboration of these sexual tensions. Freud maintained that it is this interference with the adequate discharge of the psychic component of sexual tension, i.e., its libidinal aspects, which gives rise to anxiety. Anxiety is also characteristic of psychoneurotic states, such as hysteria or obsessive-compulsive states, but here the interference with normal sexual functioning was attributed to psychic conflict or repression.

Freud held to this theory in its essential outlines until 1926, when he proposed certain fundamental revisions.

Modifications. Many workers have based their objections to Freud's first theory of anxiety on the fact that his postulates concerning the somatic or toxic aspects of sexual functioning (or malfunctioning) were naive. In fact, however, in the years since, endocrinological investigations have confirmed the existence of a variety of sexual "substances," i.e., hormones. Moreover, research findings in this area have disclosed that some of these so-called substances are even related chemically to those hormones which are involved in "fight-flight," or anxiety reactions.

Nevertheless, this theory does have certain inherent limitations. First, it contradicts a basic aspect of the psychoanalytic concept of the psychoneuroses: Freud postulated that in the psychoneuroses anxiety is the result of sexual repression, which, of course, implied that repression precedes anxiety. But what causes repression? Freud had also stated that repression arose in response to unbearable affects, which would certainly include anxiety. This, of course, implies that anxiety precedes repression and represents the basic contradiction which was the source of considerable controversy.

Second, the theory did not take into account anxiety which arises in response to realistic danger, i.e., so-called objective anxiety. Obviously, in certain situations the anticipation of external danger may cause somatic phenomena and subjective sensations of fear, which are indistinguishable from those which occur in neurotic states but are entirely unrelated to the accumulation of sexual tensions. Thus, anxiety can best be understood, not in terms of its associated sensation or its somatic expression, but in terms of whether it is precipitated by an external or an internal danger. In other words, as Freud came to realize, a comprehensive theory of anxiety must take into account its relation-

ship to the self-preservative goals of the organism: it must consider the *function* of anxiety. In a broader sense, the deficiencies associated with Freud's early theory of anxiety serve to underscore the inevitable limitations of an approach which tries to account for a phenomenon as complex as anxiety entirely on the basis of consideration of the instincts and their fate, without reference to the functions of the psychic apparatus or its relationship to the outside world.

Accordingly, in his later theory of anxiety, Freud dealt specifically with the limitations inherent in his early effort. His later theory did not discard the important relationship between frustrated sexuality and anxiety in certain neurotic conditions. Nor did it rule out the possibility that there was a direct somatic relationship between sexual conflict and anxiety, the precise nature of which had not yet been defined. However, these "economic" considerations were included within a broader theoretical framework.

The concept of narcissism. The concept of narcissism holds a transitional position in the development of psychoanalytic theory. On the one hand, it necessitated important modifications in the libido and instinct theories; on the other, it precipitated a detailed examination of the ego and its functions. Moreover, this concept has further implications which have not yet been fully explored for the understanding of psychotic patients and other patients who fail to respond to treatment.

Theoretical basis. Prior to the psychoanalytic application of the concept of self-love, the term narcissism was applied in a restricted sense to designate a sexual perversion of the type demonstrated by the Greek youth Narcissus, who fell in love with his own reflection. The first systematic discussion of narcissism appeared in Freud's writings in 1914 in his classic paper "On Narcissism." The phenomenon had provoked his interest as early as 1909, however. Moreover, on the basis of his clinical experience and his observations of the "psychopathology of everyday life," Freud had become aware of the need to expand his libido theory in order to accommodate the concept of narcissism.

In 1908, Freud observed that in cases of dementia praecox (schizophrenia) libido appeared to have been withdrawn from other persons, or objects, and concluded that this might account perhaps for the loss of contact with reality that was typical of such patients. He then speculated as to where this libido had been invested instead. The megalomaniac delusions of these patients appeared to indicate that the libido they had withdrawn from external objects was now invested in themselves, in their own egos. Concomitantly, Freud became aware of the fact that the phenomenon of narcissism was not limited to the psychoses; it might occur in neurotic and "normal" individuals as well, under certain conditions. He noted, for example, that, in physical illness and hypochondriasis, investment (or what he called "cathexis") of

the libido was frequently withdrawn from other objects or persons and from external activities and events. Similarly, he speculated that in sleep libido was withdrawn from outside objects and invested in the person's own body. It may be that in dreams the "more intense than real life" quality of the emotional experience results from libidinal cathexis of the fantasy representations of the persons who compose the dream images.

Freud was aware, of course, of the significant role of narcissism in the myths and beliefs of primitive people who attributed the occurrence of external events to the omnipotence of their own thoughts. Above all, even the most casual observation of young children will reveal the extent of their narcissism, their exclusive dedication to their own self-interest, and the tenacity with which they cling to the magical omnipotence of their thoughts.

Narcissism and the development of object relationships. Freud's observations of the narcissistic behavior of young children provided incontrovertible evidence of the role of narcissism in development and, in turn, led him to incorporate such considerations into his libido theory, outlined earlier in this section.

To begin with, while for obvious reasons the hypothesis is not testable by direct observation, Freud postulated that a state of "primary narcissism" existed at birth. That is, the neonate is entirely narcissistic; his libidinal energies are devoted entirely to the satisfaction of his needs and the preservation of his well-being. The libido which is thus invested in the infant himself was termed narcissistic, or ego libido. Later, as the infant gradually begins to recognize the person immediately responsible for his care as a source of tension relief or pleasure, libido is released for investment in that person (usually the mother). Freud called the libido that becomes available for attachment to others "object libido." Thus, essentially, the development of object relations parallels this shift from primary narcissism to object attachment, i.e., from infancy, when narcissistic libido is preeminent, to later childhood, when object libido predominates. However, it should be pointed out that some narcissistic libido is normally present throughout adult life; this is considered healthy narcissism and finds expression in the individual's "sense of well-being." Moreover, Freud observed that in a variety of traumatic situations (physical as well as psychological), e.g., actual injury or the threat of injury, object loss, or excessive frustration, libido would be withdrawn from objects and reinvested in the self. He called this renewal of libidinal investment in the individual's own body or self "secondary narcissism."

Applications to infantile sexuality. Discussion of the concept of narcissism inevitably gives rise to the central question of whether it differs essentially from autoeroticism. In fact, the difference between the two is a fundamental one: Autoeroticism refers to eroticism in relation to the subject's own body or its parts;

narcissism refers to the love of something more abstract—the self or the subject's ego.

Apart from such considerations, it should be noted that Robert Waelder has made an initial attempt to apply levels of self-love or narcissism to the developmental schemata of erotogenic zones, within the framework of Freud's theory of infantile sexuality: as it applies to the oral period, narcissism is expressed in the wish for affection and is defined as receptive narcissism; phallic narcissism designates the wish for admiration which is said to characterize this stage of psychosexual development.

Narcissism and choice of love object. Reference was made earlier to the crucial role of early object relationships in the later choice of love object. Freud found that further application of the concept of narcissism facilitated understanding of the basis for the choice of a love object in adult life. Thus, a love object might be chosen "according to the narcissistic type" that is, because she resembles the subject's idealized self-image (or his fantasied self-image), or the object chosen might be an "anaclitic type," in which case the object would resemble someone who took care of the subject during the early years of his life. Persons who themselves have an intense degree of self-love, especially certain beautiful women, have, according to Freud, an appeal over and above their aesthetic attraction. Such women supply for their lovers the lost narcissism that was painfully renounced in the process of turning toward object love. Finally, a homosexual object relationship represents still another example of a "narcissistic" object choice. In this case, the individual's choice of an object is predicated on sexual resemblance.

In summary, the concept of narcissism occupies a pivotal position in psychoanalytic theory. With the introduction of the concept of narcissism, it became obvious that the concept of the "individual," his "body," and his "ego" could no longer be used interchangeably, that further understanding and advances in psychoanalytic theory would depend on a clearer definition of the concept of self or ego. Attempts to implement such understanding brought into focus ambiguities in the concept of the ego which served to underscore the need for systematic study of its development, structure, and functions. The attention to narcissistic phenomena has also enlarged our understanding of a variety of mental disorders, as well as various normal psychological phenomena. Finally, it represents a kind of watershed in psychoanalysis for the theory of the instincts itself to which we now turn.

The theory of the instincts. When he began his work, Freud strove unceasingly to maintain psychoanalytic theory on a firm biological foundation. Only the lack of adequate scientific data induced him to relax his efforts on this score. His theory of the instincts represents one of his most important efforts to link psychological and biological phenomena, for Freud conceived of the instinct as a "borderline" con-

cept, between the mental and the organic spheres. Consequently, as mentioned earlier in connection with the term libido, Freud's use of the term instinct is not always consistent. At times, libido refers to the somatic process underlying the sexual instinct, and at other times, to the psychological representation. It has been suggested that this confusion stems, in part, from the fact that German cannot be translated accurately into English. *Triebe* are powerful, imperative strivings, such as sexuality and self-preservation, within living organisms, which are rooted in their physical nature. In contrast, the Darwinian word, "instinct" implies innate, inherited, unlearned, biologically useful behavior. Thus, the reader would do well to keep in mind the fact that Freud's *Triebe*, which has been variously translated as instinct, drive, or instinctual drive, must not be confused with the word instinct as it is used in zoology.

Freud provided his clearest definition of *Triebe* in 1915 in his paper "Instincts and Their Vicissitudes," when he wrote, "an 'instinct' appears to us as a concept on the frontier between the mental and the somatic, as the psychical representative of the stimuli originating within the organism and reaching the mind, as a measure of the demand made upon the mind for work in consequence of its connection with the body." This definition clearly points up the essential role of the instinct in psychoanalysis. Nevertheless, instinct theory remains a somewhat obscure area. The relationship between psychological and somatic processes is particularly difficult to elucidate; nor is this difficulty lessened by affirmation of the belief in the essential unity of mind and body. Psychoanalysts are, in brief, forced, just as Freud was, to delimit their theoretical constructs to the psychological parameters of human behavior. Recognition of this fact has caused an increasing number of analysts to turn to what ethologists and other students of animal behavior can teach about instincts.

The characteristics of the instincts. According to Freud, an instinct has four principal characteristics: source, impetus, aim, and object. This classification was stressed especially in his early writings when he was most concerned with the sexual instinct. In general the source of an instinct refers to the part of the body from which it arises, the site of its inception. The source, then, refers to a somatic process, the stimulus of which is represented in mental life as a drive or affect. In sexual life, the stimulus would refer to the process or factor which excites a specific erotogenic zone (the "source"). The impetus is a quantitative concept that refers to the amount of force or demand for work made by the instinct. The aim is any action directed toward satisfaction or tension release, such as the infant's activity in seeking the nipple. The object is the person or thing which is the target for this action. The object is the most variable characteristic of the instinct, insofar as it is appropriate to its task to the extent that its characteristics make satisfaction

possible. The subject's own body may serve as the object of an instinct in masturbatory activity, for example.

The classification of instincts. In the early years of psychoanalysis, as might be expected, the development of instinct theory was closely related to the clinical phenomena which Freud was investigating. From the beginning, he held to his dualistic classification of the instincts. Although initially he postulated an instinct of self-preservation, at this time (1890's) Freud was, as we have described, primarily concerned with the sexual drive, which reflected his preoccupation with the role of sexual factors in the etiology of hysteria and the psychoneuroses. Later, this relationship between the classification of instincts and clinical work became uneven. For example, in his classification of the life and death instincts, Freud concerned himself with abstract forces in nature, and his concepts in this area were not directly supported by clinical evidence.

Ego instincts. Because Freud's predominant interest was in the sexual basis of the neuroses, until approximately 1910, the self-preservative, or ego instincts, were rather neglected. However, his increasing interest in the phenomenon of self-love or narcissism led, in turn, to greater emphasis on the ego instincts. At this point, he saw narcissism as an essentially libidinal instinct; he called the remaining aspects "ego instincts," which he considered primarily nonsexual and devoted to self-preservation. Freud also felt that the ego instincts were closely associated with repression. Furthermore, at this time Freud also believed that mental conflict, which could produce symptom formation and neurosis, resulted from the clash between two instincts—the libido (or sexual) instinct, as opposed to the ego (or nonsexual) instinct. Only after he had evolved a comprehensive theory of the mental structure, and particularly the ego and the mechanisms of defense, did he abandon this conception.

The nature of aggression. Freud's discovery and early formulations regarding the ego instincts led him, in 1915, to reconsider the nature and role of aggression. Previously, Freud had considered aggression largely in terms of sadism, which he had defined as one of the sexual part or component instincts which were manifest at every level of psychosexual development. But clearly there were nonsexual aspects of sadism, and so for a time he included sadism among the ego instincts, citing, for example, the impulse to attack in order to protect oneself. Gradually, however, Freud was forced to realize that there were both sexual and nonsexual aspects of sadism. Thus, he differentiated between aggression and hate, which he assigned to the ego instincts, on the one hand, and the libidinal aspects of sadism which reverted to the sexual instinct, on the other. Sadism was further seen as the result of a fusion of sex and aggression, of love and hate, which might occur for example, in the case of thwarted desire.

But this classification gave rise to still another problem. On the basis of clinical evidence of the self-destructive tendencies of depressed patients, and self-inflicted injury among his masochistic patients, as well as his observations of the wanton destructiveness normally manifested by small children, Freud concluded that in many instances aggression or aggressive impulses were not self-preservative; therefore, they could not be properly assigned to the ego instincts. Thus, when Freud set forth his new structural theory of the mind in the 1920's, he gave aggression separate status as an instinct with a source which was largely in the skeletal muscles and the aim of which was destruction. Aggression could come about, it was true, through the frustration of libido, but in that event it was secondarily invoked, "on loan" to the sexual instincts. The elevation of aggression to the status of a separate instinct on a par with sexuality dealt a severe blow to any lingering romantic notion of the essential "goodness" of man, whose aggressive impulses were stimulated only if he was sufficiently thwarted or abused. This new formulation had other implications as well: attention then had to be given to the specific role of aggression in mental disorders and to tracing the steps through which it is "neutralized" or "detoxified." These processes have been investigated, by Hartmann and Waelder, respectively, only in the past 2 decades.

The life and death instincts. Freud introduced his theory of the dual life and death instincts, Eros and Thanatos, in 1920. As mentioned earlier, this classification of the instincts is more abstract and has broader applications than his previous concept of libidinal and aggressive drives. The life and death instincts were considered to represent the forces which underlay the sexual and aggressive instincts. As such, they represented the trends of biological organisms in general. Although Freud conceded that the death instinct was not, in itself, clinically verifiable, he felt that the validity of this concept was substantiated by certain observable phenomena. He pointed, in particular, to the tendency of individuals to repeat past behavior (a phenomenon he described as the "repetition compulsion"), even if such behavior had proven ill advised. Further evidence was to be found in the many examples of the individual's inexplicable need to suffer.

Freud defined the term "death instinct" as the tendency of organisms and their cells to return to an inanimate state. In contrast, the "life instinct," or Eros, referred to the tendency of particles to reunite, of parts to bind to one another to form greater unities, as, for example, in sexual reproduction. These forces are, therefore, analogous to catabolism and anabolism. Inasmuch as the ultimate destiny of all biological matter (with the exception of the germ cells) is to return to an inanimate state, the death instinct was thought to be the dominant force.

Apart from the fact that it implies a rather gloomy

view of life, the concept of the death instinct is the aspect of Freudian theory which has been criticized most severely, both by psychoanalysts and workers in related disciplines. This criticism has been based on the fact that, although there is an undeniable tendency toward cellular deterioration, it cannot be assumed from this that the total organism possesses a drive or instinct in that direction.

The pleasure and reality principles. In Freud's early formulations, the instincts were thought to be governed by certain regulatory principles, which were applied to all stimuli impinging on the organism, whether these stimuli emanated from within or without. Even at the time he wrote the "Project" in 1895, Freud had recognized the significance of the constancy principle, i.e., the tendency of the organism to maintain a particular level or state of equilibrium. And, along with the concept of the death instinct, Freud developed the "Nirvana principle," which postulated a tendency on the part of the organism to discharge internal tension and seek a state of rest. In 1911, he described two basic principles of mental functioning which derived from this need to maintain a state of equilibrium—the pleasure and the reality principles.

The pleasure principle, which he considered largely inborn, referred to the tendency of the organism to avoid pain and seek pleasure through tension discharge. In essence, the pleasure principle persists throughout life, but, inevitably, it must be modified by the reality principle. The demands of external reality, called the reality principle, necessitate the delay or postponement of immediate pleasure, with the aim, perhaps, of achieving even greater pleasure in the long run. The reality principle is largely a learned function; therefore, it is closely related to the maturation of ego functions and may be impaired in a variety of mental disorders which are the result of impeded ego development. Thus, here again, we come upon one of the theoretical propositions of Freud's "middle period" which underscored the need for a systematic psychology of the ego and its functions.

The theory of dreams

First recognition of the significance of dreams.

Today, dreams occupy a central position in psychoanalytic practice and theory and are the subject of expanding research interest. Nevertheless, their application in psychoanalytically oriented psychiatry and the value of dream interpretation in psychiatric treatment have not been clearly elucidated.

Freud first became aware of the significance of dreams in therapy when he realized that in the process of free association his patients frequently described their dreams of the night before or of years past. He then discovered that these dreams had a definite meaning, although it was disguised. And, finally, Freud found that encouraging his patients to freely

associate to dream fragments was more productive than their associations to real life events, insofar as it facilitated the disclosure of unconscious memories and fantasies.

Freud's monumental publication in 1900, *The Interpretation of Dreams*, included much of the data derived from his clinical experience in this area, as well as the insights he acquired by free association to his own dreams. On the basis of these data, he concluded that a dream, like a psychoneurotic symptom, is the conscious expression of an unconscious fantasy or wish which is not readily accessible to the individual in waking life. Thus, while dreams were considered one of the "normal" manifestations of unconscious activity, they were shown later to bear some resemblance to the pathological thoughts of psychotic patients in the waking state. The dream images represent the unconscious wishes or thoughts disguised through symbolization and other distorting mechanisms. Earlier, Freud had postulated the existence of a "censor" which excluded unconscious wishes during conscious states and which in sleep compelled the transformation of unconscious wishes into the disguised conscious form of the dream as experienced by the sleeper. Freud assumed that this censor was in the service of the ego; that is, he considered it a self-preservative function which was in accord with his belief that reason and volition presided over these functions. With the development of ego psychology, the activities of the censor, along with the manifestations of repression, displacement, and symbolism in waking life, have been included among those functions of the ego and superego which may lie outside the individual's conscious awareness.

Analysis of dream content. The analysis of dreams elicits material which has been repressed or otherwise excluded from consciousness by the defensive activities of the ego. The dream, as it is consciously recalled, is but the end result of the unconscious mental activity which occurs during sleep and which, because of its intensity, threatens to interfere with sleep itself. But, instead of waking, the sleeper dreams. We call the conscious experience during sleep (i.e., the dream), which the sleeper may or may not recall after waking, the "manifest dream," and refer to its various elements as the "manifest dream content." The unconscious thoughts and wishes which threaten to waken the sleeper are described as the "latent dream content." The term "dream work" is used to designate the unconscious mental operations by which the latent dream content is transformed into the manifest dream. Thus, the meaning of a dream actually refers to the latent dream content. The latent dream content which gives rise to the manifest dreams may be categorized as follows.

Nocturnal sensory stimuli. Sensory impressions, e.g., pain, hunger, thirst, urinary urgency, may play a role in initiating a dream. To illustrate, a sleeper in

a cold room, who urgently needs to urinate, may, instead of disturbing his sleep (and leaving his warm bed), dream that he has wakened, voided, and returned to bed.

The "day's residue." The second category of latent dream content comprises thoughts and ideas which are connected with the activities and the preoccupations of the dreamer's current waking life. Because of their continued activity in his unconscious, these thoughts, like sensory stimuli, tend to force waking. Instead, the sleeper may incorporate these thoughts and ideas into the manifest dream.

Repressed id impulses. In essence, however, the latent dream content derives from one or several impulses from the repressed part of the id, that is, from wishes which have their origin in the oedipal and pre-oedipal phases of development. Thus, nocturnal sensations and the "day's residue" play only an indirect role in initiating a dream. More specifically, a nocturnal stimulus, however intense, must be associated with one or more repressed wishes to give rise to a dream. Similarly, unless there is a strong link with the repressed, the concerns of waking life cannot, in themselves, give rise to a dream, however compelling their claim on the sleeper's interest and attention.

By virtue of the fact that in early childhood the psychic apparatus is still relatively immature, the relationship between latent and manifest dream content is best illustrated by the dreams of this stage of development. At this point we cannot distinguish between infantile and current conflicts, for they are one and the same. Nor is it possible to distinguish sharply conscious impulses from those which have been repressed, for the very young child's ego has not yet developed to the point where it has erected permanent defenses against the impulses emanating from the id. Thus, the classifications of latent and manifest content have less relevance with regard to the dreams of early childhood, insofar as latent content refers to unconscious material, and manifest content to that which is consciously perceived.

The significance of dreams. Throughout *The Interpretation of Dreams*, which is generally considered to be one of Freud's greatest contributions, he maintained that every dream represents a wish fulfillment. (And this hypothesis is documented by extensive clinical data, including the first complete analysis he made of one of his own dreams in 1895.) As mentioned earlier, manifest dreams are most clearly representative of the imaginary fulfillment of a wish or impulse in early childhood, before such wishes have been repressed. However, in later childhood and in adulthood, the ego defends itself against the unacceptable instinctual demands of the id, and these demands are repressed, to the degree that they appear in the manifest dream in disguised form. Nevertheless, in essence, the dream remains the same—the gratification of an id impulse in fantasy. Or, more accurately,

since motility is blocked by the sleep state, the dream enables partial (but safer) gratification of the repressed impulse.

Because this crucial wish fulfillment aspect of the dream is usually obscured by extensive distortions and disguises, it cannot be readily identified on superficial examination. And inevitably, just as Freud's theory of neurosis has been rejected by those workers who have not accepted his findings concerning infantile sexuality on which it is based, his theory of dreams has been rejected by those critics who have restricted their own investigations to the manifest elements of the dream.

The nature of dream work. Dream work comprises several processes which create the disguises and distortions which permit the translation of latent content into the manifest dream.

Dream formation. The latent content must find some means of representation in the manifest dream. Sleep brings a relaxation of repression, and, concomitantly, latent wishes and impulses press for discharge and gratification. Since motility is blocked, these repressed wishes and impulses must find some means of representation through mechanisms of thought and fantasy. Latent content achieves representation in one of two ways. First, thoughts, impressions, or memories must be found which can adequately serve to represent in visual terms these latent wishes or impulses. The individual's experience in the course of any single day provides an ample supply of such material. As mentioned earlier, when current psychological experiences are linked with repressed material, they are incorporated into the content of the dream as the "day's residue." Second, less frequently, nocturnal stimuli (e.g., hunger, pain, thirst) may be associated with repressed impulses and wishes and give rise to their representation in auditory, tactile, olfactory, or gustatory terms.

The unconscious wishes and impulses which press for discharge have been repressed because of their unacceptable nature. Because there is continued resistance to their discharge, these wishes and impulses must attach themselves to more neutral or "innocent" images, in order to pass the scrutiny of the dream censor. This is achieved by the selection of apparently trivial or unimportant images from the individual's current psychological experience, images which nevertheless are linked or associated dynamically with latent images, which they resemble in some respect. In order to facilitate the economic expression of the latent contents, and at the same time to maintain the disguise that is essential to escape the censor, the dream work employs several further mechanisms to enable these neutral images to represent repressed impulses and wishes.

Symbolism. For certain body parts or other highly cathected objects, the dreamer substitutes "innocent" images which resemble the original part in one or more essential features. For example, the snake is a familiar

symbol for the penis; or a house may symbolize the female genitalia or womb.

Displacement. The mechanism of displacement refers to the transference of emotions (cathexes) from the original object to which such emotions are attached to a substitute or symbolic representation of that object in the dream. Because it is neutral, i.e., is less invested with affect, this substitute object is more acceptable to the dream censor. Thus, whereas symbolism refers to the substitution of one object for another, displacement facilitates the distortion of unconscious wishes through the transference of affect from one object to another. At the same time, the aim of the unconscious impulse remains unchanged. For example, although the mother may be represented visually in the dream by an unknown woman (or, at least, one who has less emotional significance for the dreamer), the latent content of the dream continues to derive from the dreamer's unconscious attitudes of love and hate toward his mother. The greatest part of the distortion which enables the translation of latent impulse and wishes into manifest dream content is accomplished through the mechanism of displacement.

Projection. Through the process of projection, the dreamer's unacceptable impulses or wishes are perceived in the dream as emanating from another person. Moreover, the person to whom these unacceptable impulses are ascribed in the dream is often the one toward whom the subject's own unconscious impulses are directed. For example, the individual who has a strong, albeit repressed, wish to be unfaithful to his wife or sweetheart may dream that his "love object" has been unfaithful to him. He has thereby "projected" his own unacceptable wishes onto another person and made possible their expression in the manifest dream.

Condensation. Condensation is the mechanism by which several unconscious wishes, impulses, or attitudes are combined and find expression in a single image of the manifest dream. To illustrate, in a child's dream, an attacking monster may represent not only the dreamer's father, but also some aspects of his mother, and, finally, the monster may stand for his own primitive impulses as well. Conversely, a single latent wish or impulse may be given multiple representations in the manifest dream content. Clearly, then, condensation provides the dreamer with a highly flexible and economic device for facilitating, compressing, or expanding the manifest dream which is forged out of latent or unconscious wishes and impulses.

Affects in dreams. The affects or emotions which are associated with the latent dream content are also subjected to a variety of vicissitudes. They may not appear in the manifest dream at all or may be experienced in somewhat altered form. For example, repressed rage toward another person may take the form of annoyance or a mild dislike in the manifest dream,

or may even be represented by the dreamer's awareness that he is not annoyed. Or affect associated with the latent dream content may be transformed into its opposite in the manifest dream. A repressed longing may thereby be represented by a manifest repugnance, or vice versa; sadness may masquerade as joy, etc. In any event, these transformations of affect introduce another strong element of disguise into the manifest dream.

Secondary revision. Freud stated that dream formation preserves an example of the manner in which the primitive mental apparatus worked. As such, symbolism, displacement, and condensation are characteristic of developmentally early modes of thinking, or of the "primary process," as described below. In contrast, secondary revision, which is the final operation employed in dream formation, is the mechanism through which the absurd, illogical, and bizarre characteristics of the dream, which represent the distorting effects of symbolism, displacement, and condensation, acquire the coherence and rationality required by the subject's more mature ego. Secondary revision employs intellectual processes which more closely resemble those thought processes which govern states of consciousness; in brief, logical mental operations characteristic of the "secondary process" are introduced into the dream work.

Anxiety dreams. When Freud formulated his basic theory of dreams, he had not yet developed a comprehensive theory of the ego and of its development and functions. Consequently, his early studies of dreams emphasized their function in discharging or gratifying instinctual drives or wishes by representing their fulfillment in the dream's hallucinatory elements. However, dreams may also be approached from the standpoint of their function in avoiding tension or psychic pain. This is properly the domain of the ego, and the dream affords us an opportunity to study the structure and early development of ego functions. Freud realized only later that symbolism, displacement, condensation, projection, and secondary revision serve a dual purpose. On the one hand, they facilitate the discharge of latent impulses. On the other hand, they may be regarded as primitive defense mechanisms which prevent the direct discharge of instinctual drives and thereby protect the dreamer from the excessive anxiety and pain which would accompany such discharge.

Of course, these mechanisms which are employed to disguise latent content may fail. When anxiety pervades a dream or is so severe that it forces at least partial waking, this indicates some failure in the primitive defense operations of the ego. An element of the latent dream content has succeeded, despite extensive dream work, in forcing its way into the manifest dream in a form which is too direct or too readily recognizable for the ego to tolerate. The ego reacts to the direct expression of repressed impulses with severe anxiety.

Punishment dreams. In the punishment dream,

which is a related phenomenon, the ego anticipates superego (conscience) condemnation, if part of the latent content which derives from the repressed impulses should find direct expression in the manifest dream. More specifically, in anticipation of the terrible consequences of the loss of the ego's control over the instincts in sleep, there is a compromise between the repressed wish and the repressing agency, i.e., the superego. The demands of the superego are satisfied by giving expression to punishment fantasies.

Recent research on physiological functioning during sleep and dream states has important implications for psychoanalytic theory. Obviously, a detailed discussion of these investigations lies beyond the scope of this section. It should be mentioned, however, that perhaps the most fundamental finding to emerge from these experiments is that dreaming is a continuous process which consumes a considerable part of the sleep period in all subjects and seems to play an essential role in the integration of normal psychological functioning. Concomitantly, a shift in emphasis is perhaps required from regarding latent drives as initiating the dream process itself to investigation of the way the instincts and ego functions determine the form of particular dreams and shape them to their purposes.

Freud's early theory of the nature and function of the mind, which is discussed below, evolved in large measure from his study of the genesis, nature, and function of dreams.

Freud's Early Theory of the Mind

Historical antecedents. The originality of Freud's theories cannot be disputed. However, it is important, nevertheless, to recognize that his early ideas derived from the scientific and philosophical concepts of his day. It was pointed out, in the introduction to this section that Freud's earliest theory of the mind, as set forth in the "Project," which was published after his death, was based on the neurophysiological concepts of brain function advanced by the Helmholtz School, which, in turn, were derived from Newtonian physics. One of the unique aspects of Freud's contribution to the study of the mind was his effort to integrate empirical biological data with the kind of psychological understanding which, with rare exceptions, had previously been left to philosophers and writers. As demonstrated in the "Project," his earliest efforts at formulating a theory of the mind were in the language of physiology. And he attempted therein to interpret systematically such phenomena as consciousness, perception, memory, thought, judgment, motive forces, and defenses against pain or displeasure in terms of shifts in quantities of excitation between various systems of neurones. For reasons stated earlier, Freud was eventually forced to abandon this effort (although he continued to believe that psychical processes never operated independently of physiological ones and that the latter even preceded the former). However, he concluded that, until methods were developed which would permit verification of the interplay between the two spheres, psychical processes should be described in the language of psychology.

Although the relationship is more difficult to trace, Freud's psychological theories also have their antecedents in the contributions of 19th century psychology and the then related discipline of philosophy.

For example, several authors have called attention to the resemblance between Freud's basic formulation of the dynamic

unconscious and a similar concept developed 70 years earlier by the German philosopher, Johann Herbart. Moreover, while ordinarily Freud might not be expected to be familiar with Herbart's work, there is evidence that he was exposed to his theories during his last year at the Gymnasium. In summary, Herbart maintained that unconscious mental processes were dominated by a constant conflict of ideas of varying intensity. Ideas, according to Herbart, could be driven out of the mind by opposing ideas; but, far from being lost, they continued to assert themselves and would be treated by the subject as disturbing elements requiring self-preservative efforts.

Freud had also studied the writings of Gustav Fechner, whom he greatly admired, and whose psychology was based on Herbart's theories. Fechner, too, believed in unconscious processes which existed below "threshold" and needed to attain a certain intensity before they reached consciousness. The famous comparison of the mind with an iceberg nine tenths under water originated with Fechner. Fechner, in turn, had an important influence on Brücke, who maintained that "movements in the nervous system, give rise to ideas." In all likelihood, Freud had probably read the publications of some of Herbart's other followers as well, such as Wilhelm Griesinger, the prominent German psychiatrist, who believed that ideas could be absent from consciousness, and who associated the unconscious with impressions received from bodily organs. Other late 19th century writers and scholars, such as Theodor Lipps, professor of psychology at the University of Munich, wrote of the existence of unconscious mental processes. Fechner (and Herbart) exerted significant influence also on the ideas of Theodor Meynert, Freud's professor of psychiatry. Although, for Meynert, mind and brain were virtually interchangeable, he too was concerned with threshold and the circumstances under which ideas (excitations of brain cells) reached consciousness. Brain cells, according to Meynert, established connections through associations which were extended by means of the nutrition supplied by blood vessels. He also suggested the existence of a controlling agency which inhibited, or pressed back, the "bad" activity of the brain.

It is always difficult to weigh the influence of particular ideas upon the thinking of later writers. Certainly, the similarity between certain elements in Freud's early psychological theories and the earlier concepts of these men cannot be denied. The originality of Freud's contribution lies in the fact that, whereas previously these ideas were presented in the form of general theoretical statements, Freud elaborated a coherent theory of a dynamic unconscious based on detailed clinical observation of psychological phenomena and then tested the validity of his theory by applying it to other clinical problems.

Freud's topographical theory of the mind. The topographical theory, as set forth in the seventh chapter of *The Interpretation of Dreams* in 1900, represented an attempt to divide the mind into three regions, namely, the unconscious, the preconscious, and the conscious, which were distinguished from one another by their relationship to consciousness. Although the working model for this theory was similar in many respects to that set forth earlier in the "Project," the physiological language had, for the most part, disappeared. Accordingly, the data upon which this later theory was based derived from dream interpretation, analysis of the psychoneuroses, and the study of the psychopathology of everyday life,

e.g., the study of jokes, wit, slips of the tongue and other "errors."

Each of the three regions of the mind, which are sometimes referred to as the "system ucs," the "system pcs," and the "system cs," had unique characteristics which differentiated it from the others.

The unconscious. The unconscious contains repressed ideas and affects, and is characterized as follows.

1. Ordinarily, its elements are inaccessible to consciousness and can become conscious only through the preconscious, which excludes them by means of censorship or repression. Repressed ideas may reach consciousness when the censor is overpowered (as in psychoneurotic symptom formation), relaxes (as in dream states), or is fooled (in jokes).

2. The unconscious is associated with the particular form of mental activity which Freud called the "primary process" or "primary process thinking." The primary process has as its principal aim the facilitation of wish fulfillment and instinctual discharge; thus, it is intimately associated with the pleasure principle. As such, it disregards logical connections (which it readily short circuits), permits contradictions to coexist, knows no negatives, has no conception of time, and represents wishes as already fulfilled. (Primary process thinking is characteristic of very young children, for example, who are dedicated to the immediate gratification of their desires.)

The unconscious also employs the primitive mental operations of displacement and condensation, which permit rapid discharge of the mental energy attached to these repressed affects and ideas through the avenues of the preconscious and conscious systems. As defined earlier, displacement is the mechanism by which mental energy (cathexis) attached to one idea is shifted to another idea which encounters less censorship. Condensation is the process by which energy attached to more than one unconscious idea may be discharged through a single thought or image which embodies (in part, through symbolism) the characteristics of these several ideas. Condensation has thus the property of economy. The qualities of motility which are ascribed to the primary process also account for the fact that it is frequently linked to creativity.

3. Memories in the unconscious have lost their connection with verbal expression. Freud discovered in the course of his clinical work that repression of a childhood memory could occur if energy was withdrawn from it, and especially if verbal energy was removed. However, when words were reapplied to the forgotten memory trace (during psychoanalytic treatment), it became excessively cathected and could reach consciousness once more.

4. The content of the unconscious is limited to wishes seeking fulfillment. These wishes provide the motive force for dream and neurotic symptom formation.

5. The unconscious is closely related to the instincts. At the time this theory was developed, these were considered to consist of the sexual and self-preserved drives. Thus, it contains the mental representatives and derivatives of the instinctual drives, and especially the derivatives of the sexual instincts.

The preconscious. This region of the mind is not present at birth but develops in childhood, in a manner which parallels the course of ego development, as described in Freud's later structural theory. The preconscious is accessible to both the unconscious proper and the conscious. Elements of the unconscious can gain access to consciousness only by first becoming linked with words and reaching the preconscious. However, one of the functions of the preconscious is to maintain repression or censorship of wishes and desires. The type of mental activity associated with the preconscious is called "secondary process" or "secondary process thinking." In contrast to the primary process, such thinking is aimed at avoiding unpleasure, delaying instinctual discharge, and binding mental energy in accordance with the demands of external reality and the subject's moral precepts or values. It respects logical connections, and it tolerates inconsistencies less well than the primary process. Thus, the secondary process is closely allied with the reality principle, which, for the most part, governs its activities.

The conscious. The nature of consciousness was described in less detail in Freud's early theories, and certain aspects of consciousness are not yet completely understood by psychoanalysts. Freud regarded the conscious as a kind of sense organ of attention which operated in close association with the preconscious. Through attention, the subject could become conscious of perceptual stimuli from the outside world. From within the organism, however, only elements in the preconscious entered consciousness; the rest of the mind lay outside awareness. Prior to 1923, Freud also believed that the conscious controlled motor activity and regulated the qualitative distribution of psychic energy.

The dynamics of mental functioning. Freud conceived of the psychic apparatus as a kind of reflex arc, in which the various segments had a spatial relationship. The arc consisted of a perceptual or sensory end, through which impressions were received; an intermediate region, consisting of a storehouse of unconscious memories; and a motor end, closely associated with the preconscious, through which instinctual discharge occurred. In early childhood, perceptions were modified and stored in the form of memories.

According to this theory, in ordinary waking life, the mental energy associated with unconscious ideas seeks discharge through thought or motor activity, moving from the perceptual to the motor end. However, under certain conditions, such as external frustration or sleep, the direction in which the energy

travels along the arc is reversed, and it moves from the motor to the perceptual end. It thereby reanimates early childhood impressions in their original perceptual form and results in dreams during sleep and hallucinations in mental disorders. Freud called this reversal of the normal direction in which mental energy travelled in the psychic apparatus "topographical regression."

Although he subsequently abandoned this model of the mind as a reflex arc, the central concept of regression was retained by Freud and applied later, in somewhat modified form, in his theory of neurosis. This theory states that libidinal frustration results in a reversion to earlier modes of instinctual discharge or levels of fixation which were previously determined by childhood frustration or excessive erotic stimulation. Freud called this kind of reversion libidinal or instinctual regression.

Significance of the topographical theory. The topographical theory underscores, once again, the need for a more systematic concept of psychic structure. Its main deficiency lies in its inability to account for two important characteristics of mental conflict. First, Freud found that many of the defense mechanisms that patients employed to avoid pain or unpleasure, and which appeared in the form of unconscious resistance during psychoanalytic treatment, were themselves not initially accessible to consciousness. Obviously, then, the agency of repression could not be identical with the preconscious, inasmuch as this region of the mind was by definition accessible to consciousness. Second, he found that his patients frequently demonstrated an unconscious need for punishment. However, according to the topographical theory, the moral agency making this demand was allied with the anti-instinctual forces available to awareness in the preconscious.

These criticisms were among the important considerations which ultimately led Freud to discard the topographical theory insofar as it was concerned with the assignment of specific processes to specific regions of the mind. More precisely, Freud came to realize that what is more important is whether these processes belong to the primary system or the secondary system. Accordingly, those concepts included in Freud's early theory which have retained their usefulness refer to the characteristics of primary and secondary thought processes, the essential importance of wish fulfillment, the tendency toward regression under conditions of frustration, and, of course, the existence of a dynamic unconscious and the nature of its operation.

The Psychic Apparatus and Ego Psychology

At the outset of this discussion it must be emphasized that "id," "ego," and "superego" are abstract terms, the value of which lies in their operational referents. Each refers to a particular aspect of human mental functioning, for which no more useful term

has been found to date. However, unlike infantile sexuality or object relationships, id, ego, and superego are not empirically demonstrable phenomena.

Many workers have commented on the fact that Freud's attention was directed to the structure of the mind and the characteristics of ego functioning at a relatively late stage in the development of psychoanalysis. In fact, a careful review of the evolution of Freud's theoretical concepts will reveal that, from the beginning, he associated certain aspects of mental functioning with the ego, and others with the superego. However, during the years of his first great discoveries, he was concerned primarily with establishing the existence of unconscious mental processes and elucidating their nature and, concomitantly, with demonstrating the value of psychoanalysis as a potential technique for exploring the depths of the human mind. It is not surprising, therefore, that he was less concerned with the detailed study of those aspects of mental functioning which were normally accessible to consciousness, for they were already familiar to psychology; moreover, methods had already been established for their investigation. It was only when Freud discovered that all unconscious processes could not be relegated to the instincts, that certain aspects of mental functioning which were associated with the ego and superego were unconscious as well, that he turned to the study of these structural components.

Freud turned to the development of ego psychology in order that the progress of psychoanalysis might not be impeded by a lack of understanding of certain phenomena associated with this aspect of mental functioning. There is no question that his efforts have had important repercussions for the development of psychoanalysis—and for the understanding of personality and behavior in general. Ego psychology is not, in itself, associated with new insights which might conceivably approach the magnitude of Freud's earlier discoveries. At the same time, however, in the course of its development over the past 30 or 40 years (and particularly in the years since World War II), ego psychology has helped to refine psychoanalytic theory; more specifically, it has served to organize, to codify, to place in a systematic conceptual framework the vast amount of data derived from psychoanalytic investigation. In addition, contributions to ego psychology during this period have led to significant improvements in psychoanalytic treatment techniques.

The historical development of ego psychology.

The evolution of the concept of the ego within the framework of the historical development of psychoanalytic theory can be divided into four phases. The first phase, which ended in 1897, coincided with the development of early psychoanalytic concepts. The second phase, from 1897 to 1923, spanned the development of psychoanalysis proper. During the third phase, in the years from 1923 to 1937, Freud developed his theory of ego psychology and, concurrently, his later theory of anxiety. Finally, the fourth phase in

the evolution of the concept of ego psychology began with Freud's death and reflects the contributions of Anna Freud, Heinz Hartmann, Ernst Kris, David Rapaport, Erik Erikson, and other contemporary psychoanalysts who may be credited with the development of a general psychology of the ego.

First phase: Early concepts of the ego. In the initial phase in the development of psychoanalytic theory, the ego was not always defined precisely. Rather, it referred to the dominant mass of a person's conscious ideas and moral values, as distinct from those impulses and wishes which were repressed. Thus, the ego was considered to be concerned primarily with defense, a term which was soon replaced by repression, with which it was then considered to be synonymous. In the neurophysiological language of the "Project," the ego was described as "an organization... whose presence interferes with passage of quantities [of excitation]." Translated into the language of psychology, the ego constituted a defense which had been erected against ideas which were unacceptable to consciousness. These ideas, in turn, were found to be primarily sexual in nature; and, initially, it was thought that they had been engendered by premature sexual trauma and seduction. Because the memory of such traumata led to the arousal of unpleasant affects, they evoked a defensive response and repression of the original thoughts. However, the repression of ideas led to a damming up of energy and the production of anxiety. In a sense, then, the function of this "early ego" was contradictory. Its primary purpose was to reduce tension and avoid unpleasant affects associated with sexual thoughts; but in the process, it evoked another, equally unpleasant affect, anxiety.

It will be recalled that until 1897 Freud believed his patients' accounts of the traumatic sexual experiences they had suffered in early childhood. And he saw the ego, in its task of warding off the memories of these events, as motivated by considerations involving the individual's relationship with the real world, or, more accurately, with its ideational representations. With the collapse of Freud's seduction theory, investigation of this aspect of ego functioning was suspended. Only recently, with increasing interest in ego psychology, has the important role of the ego in mediating the individual's relationship with the outside world of events and human relationships become a focus of study once more.

Second phase: Historical roots of ego psychology. In the years dedicated to the development of "psychoanalysis proper" the analysis of the ego as such received little direct attention, for Freud during this period was concerned primarily with the instinctual drives and their transformations. Consequently, references to defense or defensive functions are much less frequent. However, as indicated earlier, there were areas of confusion in Freud's early theory of the instincts and contradictions in his theory of the mind; the clarification of these concepts required further elucidation of the function of the ego and the nature of its organization.

In regard to the sexual instinct, in 1915 Freud discussed the vicissitudes to which this instinct might be subjected as it sought expression. These included reversal into its opposite (for example, an active, sadistic impulse might be changed to a passive, masochistic one); turning upon the subject's own self (for example, the love for the object might be directed toward the self, instead); the instinct might be repressed; or, finally, the instinct might be subjected to sublimation. When they are approached from the standpoint of the ego, each of these vicissitudes might be viewed as a defense mechanism. The ego's relationship to reality is particularly relevant in this connection: As noted earlier, the concept of the secondary process implies the ability to delay discharge of the instinctual drives, in accordance with the demands of external reality, a capacity which was later ascribed to the ego. Progression to the reality principle from the pleasure principle in childhood involves a similar capacity to postpone gratification and thereby to conform with the requirements of the outside world. We have seen, too, that the important relationship of libido to a self which has not yet been completely defined, as postulated in the theory of narcissism, calls for a clearer understanding of this self or ego. According to the topographical theory of the mind, the preconscious, which, by definition, was accessible to consciousness, was held responsible for censorship (which in many instances was an unconscious operation), thereby requiring a new formulation of the agency performing this function. Another problem arose in relation to the ego or self-preservative instincts held responsible for repression: presumably, the instincts were responsible for defense, but surely this task belonged to the ego.

Finally, if neither the preconscious nor the ego instincts were solely responsible for repression or censorship, how was repression achieved? Freud tried to answer this question in 1915 by postulating that ideas are maintained in the unconscious by the withdrawal of libido or energy (cathexis). But in the manner characteristic of unconscious ideas, they constantly renew their attempt to become attached to libido—and reach consciousness. Thus, the withdrawal of libido must be constantly repeated. Freud described this process as “anticathexis” or “counter-cathexis.” But, again, if such counter-cathexis is to be consistently effective against ideas in the unconscious, it must be permanent and must itself operate on an unconscious basis. Understanding of the psychic structure (i.e., the ego) which could perform this complicated function was clearly called for and constituted still another indication of the need for the development of ego psychology.

The third and fourth phases: Development of ego psychology. During the third phase, Freud evolved his theory concerning the structural components of the mind, which was to be the foundation of ego psychology, and revised his theory of anxiety on the basis of these new formulations. The fourth phase refers to the major contributions to this area of psychoanalysis by Freud's followers. Both of these crucial phases in the development of ego psychology are discussed in detail below.

The structure of the psychic apparatus. From a structural viewpoint, the psychic apparatus is divided into three provinces, designated as ego, id, and super-ego, which are distinguished by their different functions. The main distinction lies between the ego and the id. The id is the locus of the instinctual drives. It is under the domination of the primary process; and, therefore, it operates in accordance with the pleasure principle, without regard for reality. The ego, on the other hand, represents a more coherent organization, the task of which is to avoid unpleasure and pain by

opposing or regulating the discharge of instinctual drives to conform with the demands of the external world. In addition, the discharge of id impulses is opposed or regulated by the third structural component of the psychic apparatus, the superego, which contains the internalized moral values and influence of the parental images.

The ego. It was pointed out earlier in this discussion that those conscious and preconscious functions which are typically associated with the ego, e.g., words, ideas, logic, did not account entirely for its role in mental functioning. The discovery that certain phenomena which emerge most clearly in the psychoanalytic treatment setting, specifically, repression and resistance, could themselves be unconscious, pointed up the need for an expanded concept of the ego as an organization which retains its original close relationship to consciousness and to external reality and yet performs a variety of unconscious operations in relation to the drives. Once the scope of the ego had been thus broadened, consciousness was redefined as a mental quality which, though exclusive to the ego, constitutes only one of its qualities or aspects.

No more comprehensive definition of the ego is available than the last one Freud was to give in 1938 in *An Outline of Psychoanalysis*:

Here are the principle characteristics of the Ego. In consequence of the pre-established connection between sense and perception and muscular action, the ego has voluntary movement at its command. It has the task of self-preservation. As regards external events, it performs that task by becoming aware of stimuli, by storing up experiences about them (in the memory), by avoiding excessively strong stimuli (through flight), by dealing with moderate stimuli (through adaptation) and finally by learning to bring about expedient changes in the external world to its own advantage (through activity). As regards internal events, in relation to the id, it performs that task by gaining control over the demands of the instincts, by deciding whether they are to be allowed satisfaction, by postponing that satisfaction to times and circumstances favorable in the external world or by suppressing their excitations entirely. It is guided in its activity by consideration of the tension produced by stimuli, whether these tensions are present in it or introduced into it.

Thus, the ego controls the apparatus of motility and perception, contact with reality, and, through the mechanisms of defense available to it, the inhibition of primary instinctual drives.

The id. Freud borrowed the term “id” from Georg Groddeck, an internist who became a disciple of psychoanalysis, but suggested, in *The Ego and the Id*, that it might have originated with Nietzsche. Originally, it stood for all that was ego-alien. Thus, in contrast to his concept of the ego as an organized, problem-solving agent, Freud conceived of the id as a completely unorganized primordial reservoir of energy derived from the instincts, which is under the domination of the primary process. However, it is not synonymous with the unconscious, since, as pointed out earlier, the structural viewpoint was unique in that it demonstrated that certain functions of the ego (i.e.,

the erection of defenses against the demands of the id) are unconscious, and that, for the most part, the superego operates on an unconscious level as well.

The superego. The origins and function of the superego are described in detail below. In brief, the superego is the last of the structural components to develop, resulting from the resolution of the Oedipus complex. As mentioned earlier, it is concerned with "moral" behavior, which is based, in turn, on unconscious behavioral patterns which were learned at early pregenital stages of development.

The structural model provides a useful means of expressing the nature of neurotic conflict. Essentially, neurotic conflict can be explained structurally as a conflict between the forces of the ego, on one hand, and the forces of the id, on the other. Most frequently, the superego participates in the conflict by allying itself with the ego and imposing demands in the form of conscience or guilt feelings. Occasionally, however, the superego may be allied with the id against the ego. This occurs in cases of severely regressed reactions, where the functions of the superego may become sexualized once more and take on the same impelling quality of the instinctual drives.

Finally, the external world may also participate in the neurotic conflict, in that it may be perceived by the ego as an instinctual temptation, or the "voice of conscience," or both.

The origins of the id. Freud postulated that the infant is endowed with an id, with instinctual drives which seek gratification, at birth. The infant does not, however, have the capacity to delay, control, or modify these drives. Similarly, in the matter of coping with the external world, it is completely dependent on the "egos" of other persons in its environment.

Origins of the ego. If we define the ego as a coherent system of functions for mediating between the instincts and the outside world, we must concede that the newborn has no ego. Developmental ego psychology is then faced with the problem of explaining the processes which permit the modification of the id and the concomitant genesis of the ego. Freud believed that the modification of the id occurs as a result of the impact of the external world upon the drives. The pressures of external reality enable the ego to appropriate the energies of the id to do its work. In the process of formation the ego seeks to bring the influences of the external world to bear upon the id, to substitute the reality principle for the pleasure principle, and thereby contributes to its own further development. In summary, Freud emphasized the role of the instincts in ego development, and particularly the role of conflict. At first, this conflict is between the id and the outside world; later, it is between the id and the ego itself.

More recently, Heinz Hartmann and his co-workers have expanded and modified this theory by postulating the existence of primary autonomous ego functions, the development of which is independent of the

drives and of conflict. More specifically, Hartmann and his co-workers, Ernst Kris and Rudolph Loewenstein, have suggested that the ego does not differentiate from the id, *per se*, but that both develop from a common matrix. It follows then, that the rudimentary apparatuses which underlie these primary autonomous ego functions, such as perception, motility, memory, and intelligence, are present at birth. This concept further implies that there may be congenital or genetically determined variations in ego functions. Although this hypothesis was, in fact, advanced by Freud in 1937, it has been greatly expanded and elaborated on by Hartmann and his colleagues over the past 25 years. Thus, a genetic view has been added to the theory of ego development.

In addition, Hartmann has elaborated on the role of these rudimentary ego apparatuses in the infant's coordinations with the object and the environment for the satisfaction of instinctual needs and drives. These early coordinations are the bases for what Hartmann has described as the adaptive function of the ego, that is, its function as mediator between external reality and the needs and demands of other psychic systems, i.e., id and superego. The adaptive functions of the ego are related to Hartmann's concept of ego development. The optimal functioning of the organism requires the balance of these controlling forces: ego autonomy from the demands of the id, and ego autonomy from the demands of the environment.

The evolution of the ego

The body ego. At first, the infant is unable to differentiate its own body from the rest of the world. That is, it cannot distinguish between its own proprioceptive and other subjective perceptions and reality, *per se*. Body and mind are one, in the sense that perceptual stimulation is a prerequisite for somatic development. The ego begins with the child's ability to perceive his body as distinct from the external world. From this point on, it is concerned with the ordering of reality into subjective and objective phenomena, and with awareness of the relationship between these phenomena and of other complex relationships between current apperceptions and their memory.

Developmental determinants. Much of contemporary psychoanalytic research has been devoted to the elucidation of those factors which facilitate or impede the development of ego functions. Investigations in this area (which have included the direct observation of infants) have provided considerable evidence of the relationship between gratification and frustration of drives and needs in the early months of life and the future "fate" of the ego. Concomitantly, the crucial importance for ego development of adequate satisfaction of the infant's libidinal needs by the mother (or mother surrogate) has been stressed repeatedly. However, although it is less clearly understood and appreciated, a certain amount of drive frustration in infancy and early childhood is equally important for

the development of a "healthy" ego. There is much evidence that maternal deprivation at significant stages of development will lead to the impairment of ego functions to varying degrees. But overindulgence of the child's instinctual needs will interfere with the development of the ego's capacity to tolerate frustration, and, consequently, with its ability to regulate the demands of the id in relation to the outside world.

Identification and introjection. Within this framework, psychoanalysis has described two psychic mechanisms which are specifically involved in the development of ego functions. The loss of the loved object, or of a particularly gratifying relationship with the object, is a painful experience at any stage of life, but it is particularly traumatic in infancy and early childhood, when the ego is not yet strong enough to compensate for the loss. Yet, in the early years of life, the child is constantly subjected to such deprivation. More specifically, while, in the normal course of events the young child does not suffer the actual loss of his parents, who are the primary objects at this stage of development, he must endure constant alterations in his relationship with them. Moreover, at each stage in his development, he must endure the loss of the kind of gratification which was appropriate to the previous phase of his maturation but must now be given up.

The child attempts to retain the gratifications derived from these earlier relationships, at least in fantasy, through the process of identification. By this mechanism the aspects or qualities of the person who was once the center of the gratifying relationship are internalized and reestablished as part of the developing ego. Freud considered identification to play a fundamental role in the development and enrichment of the ego and called the "character" of the ego a "precipitate of abandoned object-cathexes."

Identification begins in the oral phase of development, and it is closely associated with the oral incorporative mode of this early period. Thus, the image of the loved object may be "taken inside," much as the child first "took in" the food provided by the loved object. The psychological mechanism of symbolic incorporation, that is, the "taking in" of another person or of his or her qualities, is called introjection, and, in fact, this mechanism continues to influence character development long after the oral period.

There is some difference of opinion as to whether identification, as it applies to ego development, must be accompanied by introjection. Some authors believe, for example, that the expansion of the ego can result from direct imitation, without involving incorporation-introjection processes. On the other hand, Melanie Klein and her followers, who have studied the processes of incorporation and introjection extensively, credit very young infants with the capacity for complex processes of introjection and postulate that these mechanisms play a fundamental role at every stage of development. Clinical studies by the Kleinian

group of the mechanisms of incorporation and introjection have greatly enhanced our understanding of the distortions in these mechanisms in psychosis.

Freud also suggested that identifications may occur out of love, rather than loss, simultaneously with object cathexis; that is, identification may occur before it has become necessary to give up the object. An example of this form of identification would be the hysteric who assumes the traits of her lover, or the husband (or wife) who takes on the characteristics of his spouse. In these instances the mechanism of identification serves to strengthen the ego, just as it does in the early stages of development. In this connection, too, increasing attention has been given in recent years to the infant's very early identification with the primary object (i.e., the mother), the close relationship between this phenomenon and the child's initial differentiation of himself from the object, and, concomitantly, his progress from a state of primary narcissism to the beginning of early object relationships.

It must be emphasized that the types of identification described above lead to the strengthening of the ego and are compatible with the development of healthy object relationships. On the other hand, identification with the aggressor is a defensive maneuver, based on the child's need to protect himself from severe anxiety experienced in relation to the object. The child identifies with, and incorporates the characteristics of, the feared person, who is perceived as his attacker, and upon whom he is dependent, so that he may become allied with the aggressor rather than be his victim, in order that he may share in his power rather than be powerless before him. Such identifications may impoverish the ego by burdening it with negative introjects; their contribution to the formation of rewarding object relationships and the development of ego skills is questionable.

Again, mechanisms such as identification with the aggressor are significant in that they direct our attention to the importance of the characteristics and qualities of the object itself for the child's ego development. While Freud did not investigate this aspect of ego development in detail, it has been the focus of increasing attention in recent years, particularly in connection with the etiology of childhood psychosis.

Finally, a special type of identification with the parental imago occurs as a concomitant of the resolution of the oedipal conflict and gives rise to the formation of the superego, as described below. However, ego development does not, of course, end in the oedipal phase. The latency period, in particular, is an important "growth phase" for the acquisition of new ego strengths through learning, through the exploitation of motor skills, and through the development of a variety of object attachments and constructive identifications.

The significance of zones and modes in ego development. Erik Erikson has made a major contribution to the zonal-modal model of ego development. He

has postulated a parallel relationship between specific phases of ego or psychosocial development and specific phases of libidinal development (during which particular erotogenic zones are the loci of stimulation). This relationship may be projected to extend throughout the life cycle. Erikson's epigenetic theory of ego development describes the life tasks appropriate to specific phases of development. The characteristic successful or unsuccessful performance of these tasks has important implications for future development. For example, if task solution is successful in the oral period, basic trust will be established; if task solution is unsuccessful, mistrust will be the result, with concomitant impairment in ego functioning during the later stages of development. Autonomy versus shame and doubt are the extremes in the anal period; initiative versus guilt in the phallic phase; industry versus inferiority in latency; identity versus identity diffusion in adolescence; intimacy versus isolation in young adult life; generativity versus stagnation in adulthood; and integrity versus despair in maturity.

The functions of the ego. This discussion of ego functions is based on the preceding definition of the ego as a substratum of personality, comprising a group of functions which share in common the task of mediating between the instincts and the outside world. Thus the ego is not synonymous with self, personality, or character.

Any attempt to draw up a complete list of ego functions would be arbitrary at best. Invariably, the lists of basic ego functions suggested by various authors differ from one another, to varying degrees. This discussion will be limited to several functions which are generally conceded to be fundamental to the ego's operation.

The relation to reality. Freud always regarded the ego's capacity for maintaining a relationship to the external world among its principal functions. The character of its relationship to the external world may be divided into three components: (1) the sense of reality, (2) reality testing, and (3) the adaptation to reality.

The sense of reality. The sense of reality originates simultaneously with the development of the ego. The infant first becomes aware of the reality of his own body sensations. Only gradually does he develop the capacity to distinguish a reality outside his body.

Reality testing. This refers to the ego's capacity for objective evaluation and judgment of the external world, which depends, in turn, on the primary autonomous functions of the ego, such as memory and perception. Because of the fundamental importance of reality testing for "negotiating" with the outside world, its impairment may be associated with severe mental disorder. The development of the capacity to test reality (which is closely related to the progression from the pleasure to the reality principle), to distinguish fantasy from actuality, occurs gradually. This capacity, once gained, is subject to regression and

temporary deterioration in children, even up to grade school age, in the face of anxiety, conflict, or intense instinctual wishes. However, this should not be confused with the breakdown of reality testing referred to above, which occurs in adult psychopathology.

Adaptation to reality. This refers to the capacity of the ego to utilize the individual's resources to form adequate solutions based upon previously tested judgments of reality. Thus, it is possible for the ego to develop good reality testing, in terms of perception and grasp, but to develop an inadequate capacity to accommodate the individual's resources to the situation as perceived. Adaptation is closely allied to the concept of mastery, both in respect to external tasks and to the instincts. It should be distinguished from adjustment, which may entail accommodation to reality at the expense of certain resources or potentialities of the individual. The function of adaptation to reality is closely related to the defensive functions of the ego.

Control and regulation of instinctual drives. The development of a capacity to delay immediate discharge of urgent wishes and impulses is essential if the ego is to assure the integrity of the individual and fulfill its role as mediator between the id and the outside world. The development of the capacity to delay or postpone instinctual discharge, like the capacity to test reality, is closely related to the progression in early childhood from the pleasure to the reality principle.

Furthermore, this progression parallels the development of the secondary process, or logical thinking, which aids in the control of drive discharge. Thus, the evolution of thought, from the initially prelogical primary process thinking, to the more logical and deliberate secondary process thinking, is one of the means by which the ego learns to postpone the discharge of instinctual drives. For example, the representation in fantasy of instinctual wishes as fulfilled may obviate the need for urgent action which might not always serve the realistic needs of the individual. Similarly, the capacity to "figure things out" or anticipate consequences represents thought processes which are essential to the realistic functioning of the individual. Obviously, then, the ego's capacity to control instinctual life and to regulate thinking is closely associated with its defense function, discussed below.

Object relationships. The capacity for mutually satisfying object relationships is one of the fundamental functions of the ego. The significance of object relationships—and their disturbance—for normal psychological development and a variety of psychopathological states was fully appreciated relatively late in the development of classical psychoanalysis. The evolution in the child's capacity for relationships with others, which progresses from narcissism to social relationships within the family and then within the group, has been described by Anna Freud and Doro-

thy Burlingham in two books, *War and Children* (1943), and *Infants Without Families* (1944). Other writers have described the early stages in the relationship with the need-satisfying object and object constancy, which begins when the infant is 6 months old, and which under normal circumstances undergoes progressive development from then on. This process may be disturbed by retarded development, regression, or, conceivably, by inherent (i.e., genetic) defects or limitations in the capacity to develop object relationships. The development of object relationships is closely related to the concomitant evolution of drive components and the phase-appropriate defenses which accompany them.

The synthetic function of the ego. The synthetic function of the ego, which was described by Herman Nunberg in 1931, refers to the ego's integrative capacities; to its tendency to bind, unite, coordinate, and create; and to its tendency to simplify, or generalize. In brief, the synthetic function is concerned with the over-all organization and functioning of the ego, and it must enlist the cooperation of other ego functions in the course of its operation.

Primary autonomous ego functions. Although Freud referred to "primal, congenital ego variations" as early as 1937, this concept has been greatly expanded and clarified by Heinz Hartmann. As stated earlier, primary autonomous ego functions are based on rudimentary apparatuses which are present at birth; they develop outside of conflict with the id, in what Hartmann has called the "average expectable environment." Hartmann has included perception, intuition, comprehension, thinking, language, certain phases of motor development, learning, and intelligence among the functions in this "conflict-free" sphere. However, each of these functions might become involved in conflict secondarily in the course of development. For example, if aggressive, competitive impulses intrude upon the impetus to learn, this may evoke inhibitory reactions on the part of the ego.

The defense functions of the ego. It was pointed out earlier in this section that, in his initial psychoanalytic theoretical formulations (and, in fact, for a long time thereafter), Freud considered repression to be virtually synonymous with defense. More specifically, repression was directed primarily against the impulses, drives, or drive representations, and particularly against direct expressions of the sexual instinct, to conform with the demands of external reality. With the development of the structural view of the mind as comprising three provinces (id, ego, and superego), the function of defense was ascribed to the ego. However, only after Freud had formulated his final theory of anxiety, as described below, was it possible to study the operation of the various defense mechanisms, i.e., their mobilization in response to "danger signals." A systematic and comprehensive study of the defenses employed by the ego was presented for the first time

by Anna Freud. In her classic contribution on *The Ego and the Mechanisms of Defense*, Miss Freud maintained that everyone ("normal," as well as neurotic) employs a characteristic repertoire of defense mechanisms, albeit to varying degrees. On the basis of her extensive clinical studies of children, she described their essential inability to tolerate excessive instinctual stimulation and discussed the processes whereby the primacy of such drives at various developmental stages evokes anxiety in the ego, which, in turn, produces a variety of defenses. With regard to adults, Miss Freud's psychoanalytic investigations led her to conclude that while resistance is an obstacle to progress in treatment, inasmuch as it impedes the emergence of unconscious material, it also constitutes a useful source of information concerning the ego's defense operations.

The genesis of defense mechanisms. In the early stages of development, defenses emerge as a result of the ego's struggles to mediate between the pressures of the id and the requirements and strictures of outside reality. At each phase of libidinal development, associated drive components evoke characteristic ego defenses. Thus, for example, introjection, denial, and projection are defense mechanisms associated with oral incorporative or oral sadistic impulses, whereas reaction formations, such as shame and disgust, develop in relation to anal impulses and pleasures. Defense mechanisms from earlier phases of development persist side by side with those of later periods. When defenses associated with pregenital phases of development tend to become predominant in adult life over more mature mechanisms, such as sublimation and repression, the personality retains an infantile cast.

The repertoire of defenses that an individual characteristically employs to deal with stress-evoking situations makes an important contribution to "character." Character traits, such as excessive orderliness, are closely related to defenses but are distinguished from them by their greater role both in the over-all functioning of the personality and in situations which are not associated with specific conflicts.

While abnormalities in the development of the functioning of ego defenses, or defense mechanisms, may have a fundamental relationship to the etiology of various kinds of psychopathology, defenses are not, in themselves, pathological. On the contrary, they serve an essential function in maintaining normal psychological well-being.

Nevertheless, psychopathology may arise as the result of one of various possible alterations of normal defensive functioning. For example, in hysteria, the defense of repression is temporarily overwhelmed due to excessive sexual stimulation. This revival of previously repressed wishes calls for more desperate "piecemeal" efforts at renewed repression which result in the formation of conversion or phobic symptoms. On the other hand, the individual may show an exag-

gerated development and overuse of certain defenses, as if the danger posed by infantile sexual and aggressive impulses were as great in adult life as it was perceived to be in childhood. This kind of hypervigilance is characteristic of obsessional personalities and obsessive-compulsive neurotics. Or the development of the ego and its defenses may itself be faulty, with excessive reliance placed upon the denial-projection-distortion modes characteristic of the early oral or narcissistic phases of development. In that event, the defense mechanisms, while they permit limited functioning, particularly in the original family setting that may share these defensive patterns, cannot adequately equip the adult to meet the challenges of the external world, i.e., to form object attachments, engage in heterosexual relationships, or "cope" with vocational competition. When the defenses fail, there may be a breakthrough of direct instinctual expressions and a regression in the ego's capacity to control motility, as exemplified in the schizophrenias.

The classification of defenses. It is possible to list the defenses employed by the ego according to a variety of classifications, none of which is all-inclusive or can take into account all of the factors involved. For example, defenses may be classified developmentally, that is, in terms of the libidinal phase in which they arise. Denial, projection, and reality distortion would then be assigned to the oral phase of development, and to the narcissistic stage of object relationships. However, certain defenses, such as magical thinking and regression, cannot be pinpointed in this way. Moreover, certain basic developmental processes, such as introjection and identification, may serve a defensive function as well under certain conditions.

The defenses have also been classified on the basis of the particular form of psychopathology with which they are commonly associated. For example, within this frame of reference, the obsessional defenses would include denial and distortion. But, as pointed out above, defensive operations are not limited to pathological conditions.

Finally, the defenses have been classified according to whether they are simple (i.e., basic) mechanisms, or complex (in which event a single defense would involve a combination, or composite, of "simple" mechanisms).

A brief description of several basic and complex defenses, which are employed most frequently and have been investigated most thoroughly by psychoanalysts, is presented below.

Repression. Repression retains the central position it was accorded by Freud in relation to the defenses of the ego, and in the formation of neurotic symptoms. It results in "not being able to remember," in those instances when what is forgotten is truly unconscious. Repression is directed at id material—wishes, impulses, and affects—and is particularly prominent in the inhibition of unacceptable sexual impulses at a

phallic or genital level. Thus, repression is characteristic of hysteria, although it is used widely in other disorders as well. Finally, repression may be present in other defense mechanisms. For example, in sublimation, the original sexual drive may be repressed.

Displacement. Displacement refers to the shifting of emotion or drive cathexis from one idea or object to another that resembles the original in some aspect or quality. As a defense, displacement permits the symbolic representation of the original idea or object by another idea or object which is less highly cathected or evokes less pain. However, as mentioned above, in connection with Freud's theory of dreams, the unconscious aim of the associated impulse remains the same.

Reaction formation. The basic defense of reaction formation enables the individual to express an unacceptable impulse by transforming it into its opposite. For example, hatred of a crucial person will be transformed into overt expressions of affection. Reaction formation is characteristic of obsessional neurosis, but it occurs in other forms of neuroses as well, and if it is employed with sufficient frequency at an early stage in ego development, it may be manifested as a character trait.

Isolation. As opposed to social isolation, which refers to the absence of object relationship, isolation as a mechanism of defense refers to the splitting or separation of an idea, which is remembered, from the affect which accompanied it and is repressed.

Undoing. Undoing is an attempt to cancel out or nullify an act previously committed (in reality or fantasy) by certain counter-actions. This mechanism is characteristic, in particular, of obsessive-compulsives, whose expiatory acts, rituals, and ceremonials often represent unconscious efforts to undo some forbidden act or to cancel the effects of a wish to which they have attributed the magical power of action.

Rationalization. The individual may advance "rational" explanations (which may or may not be valid) in an attempt to hide from himself and others the actual (usually instinctually determined) motives for his behavior.

Intellectualization. This defense, which is closely related to rationalization, refers to the excessive use of intellectual processes to avoid affective experience and expression. Borderline schizophrenics, who are emotionally unstable, frequently relate to others (and themselves) on an intellectual basis in an effort to maintain their hold on reality.

Denial. The basic defense of denial is used widely in normal as well as pathological states. Its use may vary considerably, however. It may refer only to the affect associated with a particular idea or event. Or, on the other hand, there may be a massive denial of the experience itself, or its memory. In any event, this defense cannot relegate an idea or affect to the unconscious. Consequently, it is maintained at consid-

erable cost to the efficient operation of those ego functions which are related to conscious perception and the relation to reality. Consistent impairment of these functions, through the excessive use of denial, may be a precipitating factor in psychosis.

Projection. This mechanism is characteristic of psychotic states, especially paranoid syndromes, but it is also used widely under normal conditions. In projection, the individual attributes his own feelings and wishes to another person, because his ego is unable to assume the responsibility for these feelings or tolerate the painful affects they evoke. Projection is, therefore, associated with ego immaturity or vulnerability.

Regression. Through this mechanism, the ego attempts to return to an earlier libidinal phase or stage of functioning, when gratification was assured, in order to avoid the tension and conflict evoked at the present level of development. Once again, however, regression is a normal phenomenon as well. A certain amount of regression is essential for sleep and for orgasm in sexual intercourse. In addition, Ernst Kris postulated "regression in the service of the ego" as an essential concomitant of the creative process.

Counterphobic mechanisms. The ego attempts to alleviate phobic anxieties by excessive, and sometimes precipitous, activity in specific relation to the area of concern.

Withdrawal, avoidance, restriction of the ego. Anna Freud considered these mechanisms, which differ only slightly, preliminary to defense. Specifically, they attempt to deal with tension- or conflict-producing situations by enabling the ego to remove itself from these sources of anxiety instead of erecting psychological defenses to deal with them.

Introjection. As noted above, the process of introjection, whereby qualities of the loved object are internalized and become part of the subject's ego, plays a fundamental role in the early development of the ego. Introjection serves as a defense when it is used to obliterate the distinction between the subject and the loved object. Through introjection, the painful awareness of separateness, or the threat of loss that this implies, is avoided.

Identification. Identification, which plays an equally crucial role in ego development, may also be used as a defense under certain circumstances: identification with the loved object may serve as a defense against the anxiety or pain which accompanies separation from, or loss of the object, whether real or threatened. Identification may occur out of guilt, as well as love, in which event the subject identifies with a quality or symptom of the person who is the source of his guilt feelings for self-punitive purposes. Finally, the mechanism of identification with the aggressor described earlier may also be enlisted as a defense.

Acting out. In the psychoanalytic treatment setting "acting out" refers to the discharge or gratification of some aspect of an unconscious conflict through action,

without conscious awareness of the original elements of the conflict. Thus, acting out was perceived initially as a form of resistance to the treatment process. Its scope is sometimes broadened to include any substitution of action or direct gratification, including impulsive or destructive action, for remembering or talking about warded off feelings and thoughts. However, to avoid possible confusion, its use should be restricted to the living out in action of warded off memories, when the links between the action and the memory are obscure to the patient.

Sublimation. The function of sublimation extends well beyond that of a defense mechanism. It is, in addition, a fundamental outcome of the struggles among the various agencies of the mind and plays a major role in the individual's healthy psychological functioning in society. Essentially, sublimation refers to the process whereby the energy invested in a sexual aim is deflected to another aim, which is nonsexual and of greater social value. It is a defense, insofar as direct sexual gratification is renounced in favor of the other aim. Sublimation differs from other defenses, however, in that a true resolution of the conflict between the ego and the id may occur concomitantly with respect to the libidinal aim in question. In that event, sublimations may become secondary autonomous ego functions, insofar as they are independent of the drive or conflict.

Creative elaboration. The specific instinctual conflicts which arouse anxiety may be elaborated and disguised in dreams, stories, and fantasies which represent the id-ego protagonists in new relationships to each other. The drive energy is thus deflected from its original objects, and the gratification provided by the imaginative processes may be substituted for satisfaction of the original instinctual aim. This mechanism differs from sublimation in that it is not related to social values. Finally, creative elaboration may involve symbolism, identification, and other defense mechanisms.

The concept of the superego

Historical development. The concept of the superego, like the ego, has its historical origins in Freud's writings; the steps leading up to its formulation as a special agency of the mind can be traced to a paper written in 1896, entitled "Further Remarks on the Defense Neuro-Psychoses," in which he described obsessional ideas as "self-reproaches which have re-emerged in transmuted form and . . . relate to some sexual act that was performed with pleasure in childhood." The activity of a self-criticizing agency is also implicit in Freud's early discussions of dreams, which postulate the existence of a "censor" which does not permit unacceptable ideas to enter consciousness on moral grounds. He first discussed the concept of a special self-critical agency in 1914, when he published his exposition of narcissism. In "On Narcissism," Freud suggested that a hypothetical state of narcissistic per-

fection existed in early childhood; at this stage, the child was his own ideal. But as he grew up, the admonitions of others and his own self-criticism combined to destroy this perfect image of himself. In order to compensate for this lost narcissism when he had been his own ideal, or in order to recover it, the child "projects before him" a new ideal, or "ego-ideal." It was at this point that Freud suggested that the psychic apparatus might have still another structural component, a special agency whose task it was to watch over the ego, to make sure it was measuring up to the ego-ideal. The concept of the superego evolved from these formulations of an ego-ideal and a second monitoring agency to ensure its preservation.

In the following year, 1915, in *Mourning and Melancholia*, Freud speaks again of "one part of the ego" which "judges it critically and, as it were, takes it as its object." He suggests that this agency, which is split off from the rest of the ego, is what we commonly call conscience. He further states that this self-evaluating agency can act independently, become "diseased" on its own account, and should be regarded as a major institution of the ego. In 1921, Freud referred to this self-critical agency as the ego-ideal and held it responsible for the sense of guilt and for the self-reproaches which are typical in melancholia and depression. He had dropped his earlier distinction between an ego-ideal, or ideal self, and a self-critical agency, or conscience.

In 1923, in *The Ego and the Id*, Freud's concept of the superego included both these functions; i.e., the superego represented the ego-ideal as well as conscience. He also demonstrated that the operations of the superego were mainly unconscious; thus patients who were dominated by a deep sense of guilt lacerated themselves far more harshly on an unconscious level than they did consciously. The fact that guilt engendered by the superego might be eased by suffering or punishment was apparent in the case of neurotics who demonstrated an unconscious need for punishment. In later works, he elaborated on the relationship between the ego and the superego: guilt feelings were ascribed to tension between these two agencies, and the need for punishment was an expression of this tension.

In one of his last discussions of the superego in *Civilization and its Discontents*, in 1930, Freud expanded on its relationship to his evolving conception of the aggressive instinct: when an instinct undergoes repression, its libidinal aspects may be transformed into symptoms, whereas its aggressive components are transformed into a sense of guilt.

On another level, Freud related the development of the superego to the evolution of culture and to the relation of human beings to one another in society. In such moral precepts as "Love thy neighbor," which are aimed at controlling aggression, the "cultural superego" makes demands upon the individual from without, much as his personal superego dictates to

him from within. Freud believed that the cultural superego, which represents the ideals of civilization, evolved from the impressions left by the personalities of great leaders—"men of overwhelming force of mind or men in which one of the human impulses has found its strongest and purest, and therefore often its most one-sided, expression." While Freud recognized that some limits on individual satisfaction were necessarily imposed by the demands of civilization, he lamented deeply the degree to which the individual must renounce instinctual gratification in order to conform to the social requirements of the larger group. These ideas, which Freud posed very tentatively (recognizing that his application of individual psychology to society was merely by analogy), have been adopted and greatly extended (often on a rather superficial level) in various discussions of the "neurotic culture" of our time.

Origins of the superego. The superego comes into being with the resolution of the Oedipus complex. During the oedipal period, the little boy wishes to possess his mother; the little girl wishes to possess her father. However, each must contend with a substantial rival, the parent of the same sex. The frustration of the child's positive oedipal wishes by this parent evokes intense hostility, which finds expression not only in overt antagonistic behavior, but also in thoughts of killing the parent who stands in the way (along with any brothers or sisters who may also compete for the love of the desired parent).

Quite understandably, this hostility on the part of the child is unacceptable to the parents and, in fact, eventually becomes unacceptable to the child himself as well. In addition, the boy's sexual explorations and masturbatory activities may themselves meet with parental disfavor, which may even be underscored by real or implied threats of castration. These threats and, above all, the boy's observations that women and girls lack a penis convince him of the reality of "castration." Consequently, he turns away from the Oedipus situation and enters the latency period of psychosexual development. He renounces the sexual expressions of the infantile phase.

Girls, when they become aware of the fact that they lack a penis, that they have "come off badly," seek to redeem the loss by obtaining a penis (or a baby) from the father. Thus, as mentioned earlier, Freud pointed out that while the anxiety surrounding castration brings the Oedipus complex to an end in boys, in girls it is the major precipitating factor. Girls renounce their oedipal strivings, first, because they fear the loss of the mother's love, and, second, because of their disappointment over the father's failure to gratify their wish. However, the latency phase is not so well defined in girls as it is in boys. And their persistent interest in family relations is expressed in their play: throughout grade school, for example, girls "act out" the roles of wife and mother in games which boys scrupulously avoid.

Evolution of the superego. But what is the fate of the object attachments which are given up with the resolution of the Oedipus complex? Freud's formulation of the mechanism of identification is relevant here. During the oral phase, the child is entirely dependent on his parents. When he advances beyond this stage and must abandon his earliest symbiotic ties with his parents, he forms initial identifications with them (which, however, follow the anaclitic model; that is, they are characterized by dependence on another). The dissolution of the Oedipus complex and the concomitant abandonment of object ties lead to a rapid acceleration of the identification process.

One might think, following the model proposed above, that the child would identify with the parent of the opposite sex after he has been forced to renounce his oedipal object ties, and to some degree this may, in fact, occur. However, under normal conditions, the striving toward masculinity in the boy and femininity in the girl, leads to a stronger identification with the parent of the same sex. The problem is not simple; because of the bisexual potential of boys and girls, a child may emerge from the Oedipus complex with various admixtures of masculine and feminine identifications. Obviously, these identifications will have a great deal to do with his ultimate character formation and later object choices.

With specific reference to superego formation, these identifications with both parents become united and form a kind of precipitate within the ego, which then confronts the other contents of the ego as a superego. This identification with the parents is based on the child's struggles to repress the instinctual aims which were directed toward them, and it is this effort of renunciation that gives the superego its prohibiting character. It is for this reason, too, that the superego results to such a great extent from an identification with the parents' own superegos. Yet, because the superego evolves as a result of repression of the instincts, it has a closer relation to the id than does the ego itself. Its origins are more internal; the ego originates to a greater extent in the external world and is its representative.

Finally, throughout the latency period, and thereafter, the child (and later the adult) continues to build upon these early identifications through contact with teachers, heroic figures, and admired persons, who form his moral standards, his values, and his ultimate aspirations and ideals.

The child moves into the latency period endowed with a superego which is, as Freud put it, "the heir of the Oedipus complex." Its strictness at first may be compared to the imperative nature of the demands of the id before it developed. The child's conflicts with his parents continue, of course, but now they are largely internal, between the ego and the superego. In other words, the standards, restrictions, commands, and punishments which were imposed previously by the parents from without are internalized in the child's

superego, which now judges and guides his behavior from within, even in the absence of his parents.

Clearly, this initially punitive superego must be modified and "softened," so that eventually it can permit adult sexual object choice and fulfillment. Adolescence poses a unique developmental hurdle in this regard. With the heightening of sexual and aggressive drives which is characteristic during this period, there is a threatened revival of the abandoned incestuous ties to the parents and the undermining of the efforts of the superego. Often, the rebellious acting out behavior of teenagers can be understood in terms of instinctual release that the superego has failed to curb. However, their behavior may be deflected from the more threatening attachment to the parents to their representatives in the external world. In contrast, the superego of the ascetic, oversubmissive, or intellectual adolescent has responded to the threat posed by these heightened drives with renewed vigilance and intensified instinctual renunciation. The task of adolescence is to modify the oedipal identifications with the parents. Ideally, such modification will enable the choice of a love object which is not motivated entirely by the need for a parent substitute or based exclusively upon the need to rebel against their internalized imagos.

Current investigations of the superego. The exploration of the superego and its functions did not end with Freud, and such studies remain of active interest. Obviously, it is beyond the scope of this section to discuss this work in detail. However, reference should be made, in particular, to the fact that recent interest has focused on the difference between the superego and the ego-ideal, a distinction which Freud periodically revived and abandoned. Thus, at present, the term superego refers primarily to a self-critical, prohibiting agency which bears a close relationship to aggression and aggressive identifications. The ego-ideal, on the other hand, is a "kinder" agency, based, as pointed out above, on a transformation of the abandoned "perfect" state of narcissism, or self-love, which existed in early childhood and has been integrated with positive elements of identifications with the parents. In addition, the concept of an "ideal object" (i.e., the idealized object choice) has been advanced, as distinct from the "ideal self."

A second focus of recent interest has been the contribution of the drives and object attachments formed in the pre-oedipal period to the development of the superego. These pregenital (especially anal) precursors of the superego are generally thought to provide the very rigid, strict, and aggressive qualities of the superego. These stem from the child's projection of his own sadistic drives and his primitive concept of justice based on retaliation, which he attributes to his parents during this period. The harsh emphasis on absolute cleanliness and propriety that is sometimes found in very rigid individuals and in obsessional neurotics is based to some extent on this "sphincter morality" of the

anal period. Parenthetically, it should be noted that Melanie Klein's contention that the Oedipus complex, along with the superego, is well established within the 1st year of life derives from another theoretical framework and is not to be confused with the concept of pregenital precursors of the superego, as postulated by classical psychoanalytic theory.

Reformulation of the theory of anxiety. It was pointed out earlier that for many years Freud regarded neurotic anxiety as transformed libido and distinguished between such morbid distress and realistic fear of external danger. In contrast to this theory, which approached anxiety from the standpoint of the drives, the new theory, first described in 1926, attacked the problem from the standpoint of the ego. It set aside the biological approach to anxiety, which is now a subject of research chiefly in disciplines outside of psychoanalysis proper, and studied the function of this affect in relation to a variety of threats to the organism from within or without. Both "real" anxiety and neurotic anxiety were now viewed as occurring in response to a danger to the organism. In "real" anxiety the threat emanates from a known danger, outside the individual; neurotic anxiety is precipitated by an unknown danger; not necessarily external.

Danger situations. Freud distinguished two kinds of anxiety-provoking situations. In the first, for which the phenomenon of birth was the prototype, anxiety occurs as a result of excessive instinctual stimulation which the organism does not have the capacity to bind or handle. In this type of situation, which arises because of the helpless state of the individual, the excessive accumulation of instinctual energy overruns the protective barriers of the ego, and a panicky state or trauma results. These traumatic states are most likely to occur in infancy or childhood when the ego is immature; however, they may also occur in adult life, notably in psychotic turmoil or panic states when the ego organization is overwhelmed.

However, in the more common situation, which occurs after the defensive system has matured, anxiety arises in anticipation of danger rather than as its result, although the affect may be experienced subjectively as if the danger had already occurred. In these situations the emotion of anxiety serves a protective function signaling the approach of danger and may arise because the individual has learned to recognize at a preconscious or unconscious level aspects of a situation which were once traumatic. Thus, signal anxiety serves to mobilize protective measures which are then directed toward averting the danger and preventing a traumatic situation from arising. The individual may employ avoidance mechanisms to escape from a real or imagined danger from without or bring to bear psychological defenses on the part of the ego from within to guard against or reduce the quantity of instinctual excitation. According to this theory, neurotic symptoms, phobias, for example, indicate an

imperfection in the psychic apparatus: specifically, the defensive activity of the ego has not succeeded in coping adequately with the unwelcome drive. As a result, mental conflict persists, and the danger which actually arose from within is now treated as though it had its origins in the external world, at least in part. Thus neurosis is the result of a failure in the defensive function of the ego and results in a distortion of the ego's relationship to some aspect of the outside world. In psychosis, this failure of defensive function is more complete, and greater portions of external reality are perceived as dangerous; greater distortions of the ego become necessary in order to accommodate concomitant distortions in the view of the outside world.

Characteristic danger situations. Each stage of the child's development is accompanied by characteristic danger situations, "appropriate" to the issues which are pertinent to that particular phase. Thus, the earliest danger situation, which occurs when the child is most immature and helpless psychologically and physiologically, is the loss of the primary object, the person on whom he is entirely dependent. Later, when the value of the object itself is perceived, the fear of losing the object's love exceeds the fear of losing the object itself. In the phallic phase, the fear of bodily injury or castration is most prominent. And this too may be thought of as fear of a loss, in this instance, of a narcissistically treasured part of the body. In the latency period, the characteristic fear is that the parental representatives, in the form of the superego, will be angry with, punish, or cease to love the child. In each of these phases, anxiety arises in the ego. Freud also noted that, although each of these determinants of anxiety was appropriate to a particular period, they could exist side by side. Furthermore, the individual's anxiety reaction to a particular danger situation might occur after he had emerged from the developmental phase with which that situation was associated. The persistence in later years of anxiety reactions which were appropriate to various pregenital phases of development has important implications for our understanding of psychopathology.

Implications of the new theory of anxiety. The new theory of anxiety is of great potential value, in that it may help to further our understanding of a variety of psychological phenomena. At the same time, however, several fundamental questions remain unanswered. For example, we need to acquire further understanding regarding the conditions or circumstances under which the ego becomes overwhelmed by anxiety, beyond its precipitation by the anticipation of danger. Similarly, little is known about the normal psychology of anxiety; more knowledge is needed about the quantitative and qualitative factors which determine whether a given amount of anxiety (of a particular nature) will spur ego development through mobilization and stimulation of the individual's ego potential, or whether the same quantity of anxiety

(with the same quality) will impede ego development by drawing the existing ego defenses into excessive conflict formation.

It was in relation to his new theory of anxiety that Freud returned to the concept of defense, a term which he had once before abandoned in favor of repression. And it was his insight into the nature of anxiety which led to the formulation of the defense mechanisms cited above. Thus, he now saw repression as one (albeit the cardinal one) of a variety of possible defenses employed by the ego, which now also included reaction formation, isolation, undoing, etc. With the development of the new theory of anxiety, the ego was no longer a passive agency helpless in the face of the demands of the id and the outside world. Now it was credited not only with serving as a kind of advance guard which could signal danger ahead of time, but also with having at its disposal a variety of possible responses to danger from without or within which enabled the organism to meet the demands and threats of the drives and the outside world.

The Psychoanalytic Concept of Character

Historical development. The concept of character may vary widely in meaning, depending on whether it is used in a moralistic, literary, sociological, or general sense. The application of the concept in psychoanalysis has remained restricted, despite the fact that the theoretical propositions which have been advanced concerning the meaning of character have undergone an evolution which parallels the development of psychoanalytic thought. Thus, during the period when Freud was developing his theories regarding the erotogenic zones, he noted the relationship between certain character traits and particular bodily sensations or sexual components. For example, he recognized that obstinacy, orderliness, and parsimoniousness were associated with anality and with the pleasures derived from withholding or expelling feces; that ambition was related to urethral eroticism; generosity to orality, etc. And he concluded, in his paper on "Character and Anal Erotism," that permanent character traits represented "unchanged prolongations of the original instincts, or sublimations of those instincts, or reaction formations against them."

In 1913, Freud made an important distinction between neurotic symptoms and character traits: neurotic symptoms come into being as a result of the failure of repression, and the return of the repressed; character traits owe their existence to the success of repression (or, more accurately, the defense system), which has achieved its aim through reaction formation and sublimation. Later, in 1923, with increased understanding of the phenomenon of identification and the designation of the ego as a coherent system of functions, the relationship of character to ego development came into sharper focus. At this point Freud observed that the replacement of object attachments by identification, which "set up" the lost ob-

ject "inside the ego" also contributed to character formation. And 10 years later, in 1932, Freud emphasized the particular importance of identification with the parents for the construction of character, as well as superego formation.

Several of Freud's disciples made important contributions to the concept of character during this period. A major share of Karl Abraham's efforts was devoted to the investigation and elucidation of the relationship between oral, anal, and genital eroticism and various character traits. Wilhelm Reich made an important contribution to the psychoanalytic understanding of character in the 1920's when he described the intimate relationship between resistance in treatment and the character traits of the patient. Reich's observation that resistance typically appeared in the form of these specific traits anticipated Anna Freud's later formulations concerning the relationship between resistance and typical ego defenses.

Current concepts of character. The development of psychoanalytic ego psychology has led to an increasing tendency to include character and character traits among the properties of the ego, superego, and ego-ideal, although they are not synonymous with any of these. Concomitantly, the emphasis has been extended from an interest in specific character traits to a consideration of character and its formation in general. Thus, psychoanalysis has come to regard character as the pattern of adaptation to instinctual and environmental forces which is typical or habitual for a given individual. The character of a person is distinguished from the ego by virtue of the fact that it refers largely to directly observable behavior and styles of defense, and of acting, thinking, and feeling. The clinical value of the concept of character has been recognized by psychiatrists as well as psychoanalysts and, in fact, has become a meeting ground for the two disciplines.

The evolution of character. The formation of character and character traits results from the interplay of multiple factors. Innate biological predisposition plays a role in character formation in both its instinctual and ego Anlage. The interaction of id forces with early ego defenses and environmental influences, most notably the parents, constitutes a major determinant in the development of character. And various early identifications and imitations of other human beings leave their lasting stamp upon character. The degree to which the ego has developed a capacity to tolerate delay in drive discharge and neutralize instinctual energy, as a result of early identifications and defense formations, determines, for example, the later emergence of such character traits as impulsiveness. Finally, a number of authors have stressed the particularly close association between character traits and the development of the ego-ideal. In this respect the psychoanalytic concept of character parallels society's use of the term "character" in a moral sense.

The exaggerated development of certain character traits at the expense of others may lead to character disorders in later life; at other times, such distortions in the development of character traits produce a vulnerability or predisposition to the psychoses. These concepts are expanded in the following part of the section in relation to specific forms of psychopathology.

Psychopathology: The Psychoanalytic Theory of Neurosis

Psychoanalytic theories concerning mental disorder have undergone extensive expansion and modification since Freud discovered the free association method of investigation. However, these theories have retained their emphasis on the elucidation of etiological factors, rather than the mere description of symptoms. By 1906, Freud had succeeded in understanding the psychological processes underlying many mental disorders to a degree sufficient to permit him to classify them on the basis of psychopathology. At that point in his investigations, Freud's theories contained all of the major elements of present day psychoanalytic concepts of psychopathology: he had advanced initial hypotheses concerning the psychological mechanisms of neuroses, character disorders, perversions, and psychoses. Indeed, the investigations of Freud and his followers thereafter yielded only additions and minor revisions in his earlier theories on psychopathology.

Historical evolution

Early concepts. Cases of hysteria treated by the cathartic method, a modified form of hypnotherapy, led Freud to conclude that hysterical symptoms were caused by unconscious memories of events. These memories were accompanied by the strong emotions which had been elicited originally, at the time these events actually occurred, and which had not been expressed or discharged adequately. On the basis of this conclusion, Freud hypothesized that hysterical symptoms were the result of psychic traumata in individuals congenitally or genetically predisposed to the development of such phenomena. Although this theory differed from his earlier biological concept of neurasthenia, in that it provided a purely psychological explanation, it too proved to be an oversimplification.

At first, Freud believed that excessive masturbation or nocturnal emissions gave rise to the symptoms which were typical of neurasthenia, i.e., fatigue, listlessness, flatulence, constipation, headache, and dyspepsia. He distinguished anxiety neurosis, which was characterized principally by anxiety attacks, from the syndrome of neurasthenia. Anxiety neurosis was related etiologically to states of activity which produced sexual stimulation or excitement but did not provide an adequate outlet for discharge. He cited coitus interruptus or lovemaking without sexual gratification as examples. Thus, as late as 1906, Freud

believed that the symptoms of neurasthenia and anxiety neurosis represented the somatic effect of disturbances in sexual metabolism (which, most likely, were biochemical in nature) and referred to these as actual neuroses, as opposed to hysteria and obsessions, which he described as psychoneuroses. Of particular interest is the fact that these classifications stressed the etiology of these disorders, rather than symptomatology: Freud assumed that drive energies which should have been discharged in a sexual climax created a state of psychic tension too great for the ego to master, thus producing anxiety.

The relevance of clinical data for theory formation. As the free association method continued to provide new insights into the origins of psychopathology, Freud revised and expanded his theories. Psychic conflict was now recognized as an element in the production of psychoneurotic symptoms. This required that he extend his earlier theory of hysterical and obsessional symptoms as caused by a forgotten event of the past with concomitant emotions which had not been adequately discharged. Originally, Freud maintained that a psychic event or experience could be considered pathogenic if it was repugnant to the individual's conscious self, if, for example, it violated his ethical and moral standards to the degree that it must be consciously repudiated. Hysteria, most obsessions, and many phobias were understood in this way, although some phobias (such as agoraphobia) and some obsessions (such as doubting mania) were described as actual neuroses.

The theory of infantile sexuality. The fact that, almost invariably, in the course of treatment, his patients recalled a previously forgotten sexual experience which had occurred in childhood led Freud to hypothesize that mental illness was the psychic consequence of a sexual seduction by a child or an adult at an early stage in the patient's development. His assumption that sexual seduction had actually occurred proved incorrect. But the basic proposition that the roots of psychoneurosis lie in a disturbance in early sexual development remains unshaken and is the cornerstone of the psychoanalytic theory of neurotic disorder.

Further clinical study led to the conclusion that these memories of sexual seduction in childhood were actually fantasies, although the patients themselves believed in their reality. Reexamination of the data elicited through free association in this connection enabled Freud to formulate the theory of infantile sexuality, which stated that sexual interests and activities were a normal part of human psychic life from earliest infancy and were not limited to traumatic events. Nevertheless, despite these psychological findings, Freud continued to stress the importance of the patient's sexual constitution and heredity in the etiology of the psychoneuroses.

Progress in elucidating the precise nature of such constitutional factors has been very slow. In contrast, our knowledge of experiential etiological factors has increased. The discovery that infantile sexuality is a normal phenomenon narrowed the gap between the normal and the psychoneurotic and enabled Freud to elucidate the origins of the sexual perversions and their relationship to both normal and psychoneurotic functioning. The abnormal persistence in adult sexual

life of some component of infantile sexuality might lead to perversion. However, in the normal course of events, some components of infantile sexuality were repressed and others were integrated into adult sexuality at puberty, with genital primacy. Other insights followed: excessive repression creates instability, so that in later life there is a greater likelihood that precipitating events will cause a failure of repression. In that event, infantile sexual impulses will emerge from the unconscious, at least to some degree, in the form of psychoneurotic symptoms.

The psychology of dreams. Freud's study of dreams showed that the dream which the sleeper remembered, i.e., the manifest dream, represented a compromise between one or more repressed impulses and those psychic forces which opposed the entrance of such impulses into conscious thought and behavior. Neurotic symptoms represented a similar compromise with one exception: the latent, instinctual wish which underlay the manifest dream might or might not be a sexual one, but the repressed impulses which produced neurotic symptoms were always sexual. On the other hand, the meaning of neurotic symptoms, like the elements of a manifest dream, lies in their latent or unconscious content. They are disguised and distorted expressions of unconscious sexual fantasies. Part, or all, of the sexual conflict of the psychoneurotic patient is expressed in his symptoms.

Current concepts of neurosis. The theory of neurosis (used in the traditional sense to refer to hysteria, obsessional neuroses, and the phobias) is central to psychoanalytic concepts of psychopathology. Neuroses develop under the following conditions: (1) There is an inner conflict between drives and fears which prevents drive discharge. (2) Sexual drives are involved in this conflict. (3) The conflict has not been "worked through" to a realistic solution. Instead, the drives which seek discharge have been expelled from consciousness through repression or another defense mechanism. (4) The repression merely succeeded in rendering the drives unconscious; it did not deprive them of their power and make them innocuous. Consequently, the repressed tendencies have fought their way back into consciousness, disguised as neurotic symptoms. (5) Finally, an inner conflict will lead to neurosis in adolescence or adulthood only if a neurosis, or a rudimentary neurosis based on the same type of conflict, existed in early childhood.

Developmental schema of the etiology of neurosis

Early childhood. In the course of development, many vicissitudes may contribute to the future malfunctioning or malformation of the psychic apparatus. Maternal deprivation in the first few months of life may impair ego development in a manner that is particularly devastating to its integrative capacities. Failure to make the necessary identifications, either because of overindulgence or because of excessive frustration, interferes with the ego's task of mediating between the instincts and the environment, with consequent limitations of drive discharge and restric-

tion of the ego's capacity to obtain pleasure and assert itself usefully. Lack of capacity for equitable expression of drives, especially aggressive ones, may lead the individual to turn them onto himself, and to become overtly self-destructive. Inconsistency, excessive harshness, and/or undue permissiveness on the part of the parents may result in the disordered functioning of the superego. Instinctual conflict may impair the ego's capacity for sublimation, resulting in excessive inhibition of its autonomous functions. Severe conflict which cannot be dealt with through symptom formation may lead to severe restrictions in ego functioning, and the impairment of the capacity to learn and to develop new skills.

Puberty and adult love. When the ego has been weakened, a shock or traumatic event in later life which threatens survival (or appears to), especially when combined with external factors which further weaken ego resiliency, such as toxic conditions or exhaustion, may break through the ego defenses. A large amount of libido is then required to master the resultant excitation. But the libido thus mobilized has been withdrawn from the supply normally applied to external objects and from the ego itself, and this further diminishes the strength of the ego and produces a sense of inadequacy.

In summary, precipitating factors in neuroses are experiences which disturb the "balance" between warded off impulses and warding off forces. Increase in the warded off drive may be absolute, as at puberty or the climacteric, due to the physiological intensification of sexual drives at these times. Or there may be a relative increase in a specific warded off drive at the expense of other instinctual demands, as in the case of conscious or unconscious temptation or stimulation of a particular wish.

Disappointments or frustrations of adult strivings can revive infantile longings which may be dealt with through symptom formation or further regression. Decrease in the warding off forces due to fatigue, intoxication, sickness, or overexacting tasks may loosen previously effective defenses against drive derivatives and precipitate a neurotic, or even a psychotic illness. As long as the warded off instincts cannot be tolerated in consciousness, the ego has no choice but to form symptoms or to modify its aims so that the unfulfilled strivings become less urgent.

Secondary gains of neurosis. The reduction of tension and conflict through neurotic illness is the primary purpose or gain of the disorder. The ego, however, in "making the best of it," may try to gain advantages from the external world via the illness, e.g., by provoking pity in order to get attention and sympathy, by manipulating others, or even by receiving monetary compensation. Similarly, the patient may imply to others that his suffering entitles him to a compensatory reward of pleasure. These are the secondary gains of the illness.

Each form of neurosis has its characteristic and

predominant form of secondary gain. In phobias (anxiety hysteria), there is a regression to childhood, when one was still protected. Gaining attention through dramatic acting out and, at times, deriving material advantages are characteristic of conversion hysteria. Frequently, in compulsive neurosis, there is a narcissistic gain through pride in illness. In the organ neuroses (psychosomatic states), psychic conflicts are denied by projecting them onto the physical sphere. Finally, in the psychoses, the warding off of a painful idea, experience, or frustration in the outside world leads to severe regression which requires that the patient be taken care of, thus satisfying his extreme dependency needs.

Brenner has summarized the contemporary psychoanalytic concept of mental disorder as follows: "In terms of modern psychoanalytic theory, what we refer to clinically as mental disorders can best be understood and formulated as evidences of malfunction of the psychic apparatus to various degrees and in various ways. As usual, we can best orient ourselves if we adopt a genetic, or developmental approach."

Nosology

Conversion hysteria. Conversion hysteria provides a defense against overintense libidinal stimulation, by means of a transformation or conversion of psychical excitation into physical innervation. As a result, various alterations of motor function or sensation may occur. The innervation is not haphazard; it represents a genitalization of the particular part of the body associated with repressed unconscious wishes directed toward a love object. Fixation of the phallic stage of psychosexual development, a tendency to libidinize thoughts and images, and frustration in external life (in relation to strong unconscious fantasies) are etiological factors.

The change in physical function which occurs gives expression, in distorted form, to instinctual impulses which had been repressed previously. However, conversion symptoms are not simply somatic expressions of affects, but very specific representations of thoughts which can be retranslated, through the free association method, from their "somatic language" into words. The syndromes of conversion are unique in every individual; and in each instance the specific type of distortion is determined by the historical events which created the repression. The distortion mechanisms employed in dreams are employed in conversion hysteria as well, namely, condensation, symbolism, displacement, etc.

Pathogenesis and symptomatology. Usually, hysterical spells or attacks, which are rarely encountered in current clinical practice, are pantomimic expressions of rather complicated fantasies relating to the child's concept of his parents' sexual relations during the oedipal period. However, the hysterical seizure may also express pregenital actions which are regressive substitutes for the original oedipal fantasies. Some attacks are less specifically sexual and occur in the

form of convulsions; as emotional outbursts or "moods," which appear to be entirely unmotivated; or as screaming, crying, or laughing spells. Related to the seizures are various bizarre symptoms, including the sudden appearance or disappearance of normal physical needs; attacks of hunger or thirst; an urgent need to defecate or urinate; and difficulties in breathing.

In monosymptomatic conversions, the somatic innervation expresses the memory of an event which took place in the forgotten situation. For example, Breuer's patient, Anna O., had a paralysis of her arm whenever she was unconsciously reminded of her feelings for her father. (At the time her father died, she had been sitting at his bedside with her arm pressed against the chair at the side of the bed.) The motor disturbance represents a defense against an action, specifically an action which is associated with an objectionable infantile impulse. Hysterical pain may represent a signal or warning not to yield to the pleasant sensations which are associated with the memory of a painful episode. (Pain originally experienced by the patient himself recurs in the conversion symptoms as a substitute for the pleasant excitement once connected with it.) At times, the hysterical pains, imitated in the conversion symptoms, have been experienced, not by the patient but by another person with whom the patient identifies in producing his symptom. Freud's patient, Dora, illustrated hysterical identification with a rival by developing a cough like that of Frau K., with whom she unconsciously competed for Herr K. A female patient whose hysteria is due to her unresolved Oedipus complex may make an identification not with her rival, her mother, but with her beloved father. In this way the girl struggles to free herself of the frustrating love for the father; she may then seek to satisfy negative oedipal wishes by taking her mother as a love object. The most frequent form of hysterical identification takes place with an object with whom the patient has no genuine object relationship. It is formed on the basis of "identical ideological needs." Freud used an hysterical epidemic in a girls' school to illustrate this phenomenon: a girl reacts with a fainting spell to a love letter, and the other girls in the school get fainting spells as well. The unconscious meaning is: "We would like to get love letters too." Finally, there may be "multiple identifications" by a single patient, as exemplified by cases of "multiple personality" described in the literature.

Hysterical dream states are closely related to seizures. The day-dreams, which represent derivatives of the repressed oedipal fantasies, involuntarily take possession of the personality, thereby removing the patient from reality. A mixture of hysterical spells and hysterical dream states is represented by the conversion symptom of sleep-walking. The typical aim is the wish to participate in adults' sexual night life. Other alterations in states of consciousness, such as

amnesic or dissociative states, also result from the repression, or warding off, of an intolerable aspect of infantile sexual life which has been revived by current sexual stimuli. Hysterical disturbances of the senses represent an attempt to reject upsetting sexual perceptions.

Choice of neurosis. Somatic compliance symptoms described above illustrate that the entire cathexis of the objectionable impulses appears to be condensed into a definitive physical function. The choice of the afflicted region may be determined by the unconscious sexual fantasies and the corresponding erogenicity of the afflicted part, by physical injury or a change in a part of the body which increases its susceptibility, by the nature of the situation in which the decisive repression occurred, and by the ability of the organ to express symbolically the unconscious drive in question. Finally, as is well known, hysteria may imitate a wide variety of diseases, which complicates the clinical picture considerably.

Phobia. Phobia, which is often referred to as anxiety hysteria, is an abnormal fear reaction which is caused by a paralyzing conflict due to an increase of sexual excitation attached to an unconscious object. The fear is avoided by displacing the conflict onto an object or situation outside the ego system. After this displacement has occurred, the readiness to develop anxiety is bound to the specific situation which precipitated the first anxiety attack. If situations occur which duplicate or represent the original event symbolically, it will become manifest. The ego fights off the anxiety through states of inhibition such as impotence and frigidity or through avoidance of objects that have become connected with unconscious conflicts either through historical associations or through their symbolic significance.

Pathogenesis. The manifestations of phobias are protean. As the degree of displacement increases, the connection between the fear situation and the original instinctual conflict becomes more concealed. The feared situations or persons have a specific unconscious significance and in a distorted way symbolize either a forbidden gratification, a punishment for an unconscious impulse, or a combination of both. The advantage of the displacement is that the original offensive idea does not become conscious. In Freud's famous case history of "little Hans," the boy's fear of a horse instead of his father helped him to avoid hating his father, by whom he was threatened, and whom he also loved. Projection from an internal danger onto an external one such as a wolf, for example, which exists chiefly in the imagination, has another advantage: wolves are seen only in picture books, which need not be opened, or at the zoo, where one does not have to go very often. Although the objects or situations from which the phobic individual flees represent the threatening parents primarily, he is also in flight from his own impulses; even the fear of castration, which

is perceived as an external threat, arises primarily as a consequence of the child's own phallic impulses.

Symptoms. The patient's history, the nature of the drives warding off, and the mechanisms of defense employed determine the clinical symptoms. Phobias about infection and touching often express the need to avoid dirt and show that the patient has to defend himself against anal-erotic temptations. Fear of open streets and stage fright may be a defense against exhibitionistic wishes. Anxieties about high places, closed places, falling, cars, trains, and airplanes are developed to fight pleasurable sensations connected with stimulation involving the equilibrium.

As a rule, the first neurotic reactions in children have the character of anxiety hysteria. With regard to adults, typically, the onset of phobic reactions occurs at a time of crisis in the sexual life. Fixation at the phallic stage and sexual frustrations, the presence of an external factor which may weaken the ego, increases in libidinal excitement, and a particular susceptibility to anxiety reactions are the most common etiological factors.

Obsessional neurosis. The obsessional or obsessive-compulsive neurosis is characterized by persisting or urgently recurring thoughts and repetitively performed behavior which bear little relation to the patient's realistic requirements and are experienced by him as foreign or intrusive.

Pathogenesis. The obsessional neurosis comes about as a result of the separation of affects from ideas or behavior by the defense mechanisms of undoing and isolation, by regression to the anal-sadistic level, or by turning the impulses against the self. As a defense against a painful idea in the unconscious, the affect is displaced onto some other, indirectly associated idea, one more tolerable, which in turn becomes invested with an inordinate quantity of affect. As mentioned earlier in this section, Freud described obsessional ideas as self-reproaches which have reemerged from repression in a transmuted form. He also suggested that they relate to some sexual act which was performed with pleasure in childhood. Nevertheless, in early childhood, there are few indications of the development of obsessional tendencies. Moreover, usually, at the time such trends develop in latency, no self-reproach is attached to the memory of earlier pleasurable activities. However, a primary defense system (i.e., the superego) develops at approximately this point, which consists of general conscientiousness, a sense of shame, and self-distrust, now referred to as character defenses. A period of apparent health or successful defense functioning may occur before the onset of the illness. The period of illness proper is distinguished by the return of repressed memories in the form of obsessive-compulsive symptoms, that is, by the failure of the character defenses. The obsessional ideas which emerge are derivatives which express the warding off drives. Sometimes they preserve their char-

acter as impulses. Sometimes the original drive cannot be readily discerned, and the patient is aware only of ideas that must be thought about, which indicates that the energy associated with the original impulse has been diverted to a more neutral idea.

In other words, compulsions and obsessive symptoms are a condensation of both instinctual and anti-instinctual forces. In some instances, in obsessions related to incestuous or murderous ideas, for example, the manifest clinical picture reveals the direct instinctual aspect more clearly. In other instances (e.g., when symptoms obviously express the defensive or punishing commands of the superego), the anti-instinctual forces are predominant. Actually, the individual tries to protect himself from the threatened loss of his self-respect, which, in turn, is precipitated by the guilt feelings occasioned by the disapproval of the superego, rather than the loss of love or castration. As mentioned above, the onset of obsessive-compulsive neurosis occurs relatively late in childhood because it depends on the formation of the superego. The introjection of the parents into the superego explains the relative predominance of punitive and expiatory symptoms which affect the total personality of the patient.

A phobia may be transformed into an obsession: certain situations must be avoided by the phobic person, and he exerts great effort to ensure this avoidance, to the degree that in time these efforts assume an obsessive-compulsive character. Other obsessions may then develop which are so remote from the situation which was the original source of fear that the avoidance is assured. For example, touching rituals may replace taboos; washing compulsions take the place of the fear of dirt; social rituals supercede social fears; sleeping ceremonials replace fears of falling asleep.

It has already been stated that in the obsessive-compulsive neurosis, fixation of libido at the anal-sadistic stage has occurred. Concomitantly, ego development has been arrested at the accompanying stage of omnipotence of thought. Factors which result in frustration of post-anal-sadistic impulses (usually of a phallic nature) or which impede more mature ego functioning will lead to the precipitation of overt symptomatology. Defenses are first directed against the phallic-oedipal drives, but as regression occurs they are directed against the anal-sadistic impulses themselves. External circumstances which remobilize the repressed infantile sexual conflicts and disturb the hitherto effective equilibrium between the repressing and repressed forces may precipitate acute cases of the neurosis. The more frequent chronic type continues more or less without interruption from adolescence. However, particular external circumstances may precipitate exacerbations from time to time if the defenses become less effective, or the impulses defended against more unbearable. Freud's most important clinical study of this syndrome was his case his-

tory of the "Rat Man" ("Notes on a Case of Obsessional Neurosis").

Organ neuroses (psychosomatic disorders). Between the realm of organic disorders from known physical causes and the group of conversion disorders, there exists a large group of syndromes which are characterized by functional, and even anatomical, alterations. Originally, these were called "organ neuroses"; they are presently referred to as "psychosomatic disorders." Peptic ulcer, asthma, and ulcerative colitis have been regarded as typical examples of psychosomatic disorders.

The genesis of psychosomatic disorders. Many theories have been advanced to explain the origins of these phenomena. For one, psychosomatic symptoms have been described as affect equivalents, which represent dammed up emotions or their symbolic representation, which cannot be discharged through behavior or speech and which find expression instead along somatic pathways in the form of a structural or functional alteration in an organ or organ system. According to this theory, anger or sexual excitement, as well as anxiety, may be supplanted by sensations and other changes in the intestinal, respiratory, or circulatory apparatus. For example, cardiac neurosis is considered to be an anxiety equivalent. Although it has some validity, the theory of affect equivalents is generally regarded as an oversimplified explanation of the multitude of complex interrelationships between psychological and somatic processes which obtain in these disorders and which, as yet, are not completely understood. Furthermore, although all affects are carried out by motor or secretory means, the physical manifestations of any given disease may occur without a clearly established etiological relationship to specific mental or emotional experiences. The difficulties are compounded by the fact that the psychosomatic disorders, themselves, may bring about various pathological adaptive responses in the individual, i.e., the "pathoneuroses" described by Ferenczi, in which event it is difficult to determine whether the emotional disorder preceded the physical, or vice versa.

Current issues. The normal interrelationship between hormonal physiology and instinctual phenomena is a subject of much current study and interest. Unfortunately, space limitations preclude a detailed discussion of the rationale underlying this research. Briefly, those workers who are involved in such investigations maintain that, given a predisposition, or susceptibility, to psychosomatic disorders in a particular individual, the inhibition of specific affects may lead to certain hormonal secretions, to change in physical functions, and, eventually, to alteration in the tissues themselves. Different unconscious affects, as they occur in specific disorders, probably cause quantitative and qualitative differences in hormone secretion and thereby bring about in the vegetative

nervous system a complex combination of stimulatory (sympathetic) and inhibitory (parasympathetic) responses.

Character (personality) disorders. It was stated earlier in this section that, in its psychoanalytic sense, character refers to the ego's habitual mode of bringing into harmony the tasks presented by internal demands and the external world. When and how the ego acquires the qualities which enable it to adjust, first, to the demands of the instinctual drives and of external reality, and later to the demands of the superego could be the subject of a separate treatise. Concomitantly, the description of pathological character types may be complex and rather confusing in that discrete types without overlap rarely exist.

Definition. A particular character pattern, or type, becomes pathological when its manifestations are exaggerated to the point that behavior destructive to the individual or to others results or the functioning of the person becomes distorted or restricted, so that it becomes a source of distress to himself or others. Those character types which are of particular clinical interest are described briefly below. Character disorders are also known as personality disorders and are discussed elsewhere in this book under the latter designation.

Phobic characters. These individuals limit their reactive behavior to the avoidance of the situations which they yearned for originally. Thus, certain external situations are avoided, as is true of neurotic phobic behavior. In addition, however, internal reactions, such as rage or love, or all intense feelings may be subjected to phobic avoidance.

Compulsive characters. Reaction formations are characteristic of these individuals. Typically, they attempt to overcome sadism by kindness and politeness, to conceal pleasure in dirt by rigorous cleanliness. As the result of isolation there is a lack of adequate affective response and a restriction in the number of available modes of feeling. Object relationships are of an anal-sadistic nature.

Hysterical characters. Hysterical characters have been described as persons who are inclined to sexualize all relationships, who tend toward suggestibility, irrational emotional outbreaks, chaotic behavior, dramatization, and histrionic activity.

"Cyclic" characters. These persons exhibit periodic mood swings, from depression to varying degrees of elation. Cyclic characters are particularly concerned with unresolved oral needs and conflicts.

Schizoid characters. The schizoid character evidences a heightened narcissism and the withdrawal of libido from outside persons into his own thoughts and feelings. He may manifest an intense need for approval or an omnipotent narcissism which is independent of the opinions of other people and is associated with limitations and distortions in the reality testing function of the ego.

Impulse-ridden characters. Finally, the impulse-

ridden character, who is frequently encountered in psychiatric practice, habitually discharges tension or avoids inner conflict by urgent activity, which is sometimes of a destructive or self-destructive nature.

Perversions. Perversions are manifestly sexual in character. When the pathological impulses are released, orgasm is achieved. As we have noted, the sexual aims in adult perversions correspond to components of the sexual drives of children. But the genesis of perversion cannot be attributed solely to the hypertrophy of an infantile, partial instinct. Factors of anxiety at phallic and pregenital levels, bisexuality, identifications, structural considerations, and external circumstances all play a part in determining the genesis of perversion. These factors are described only very briefly below; the detailed discussion which they obviously require lies beyond the scope of this section.

Homosexuality. In essence, homosexuality may be considered a vicissitude of the Oedipus complex, in that the resolution of the oedipal conflict is based on the negative oedipal constellation. Specifically, the child has identified with the parent of the opposite sex and chosen the parent of the same sex as a love object. Narcissistic factors also play an important role in homosexuality: the choice of an object is based, in part, on its sexual resemblance to the individual himself.

Fetishism. Fetishism refers to the veneration of inanimate objects which symbolize parts of the body of an ambivalently loved person.

Transvestism. The transvestite finds dressing in garments which are characteristic of the opposite sex a source of sexual excitement.

Exhibitionism. Exhibitionism is the deliberate exposure, usually compulsive, of sex organs under inappropriate conditions.

Voyeurism. The voyeur achieves sexual gratification by watching the sexual activities of others.

In their extreme form, sexual submissiveness, sadism, and masochism represent perversions. These phenomena are discussed at length in the psychoanalytic literature.

Impulse neuroses. The impulse neuroses, which are related to perversions, involve impulsive actions which, though not necessarily overtly sexual, serve the purpose of avoiding or mastering some type of pregenital anxiety which is intolerable to the ego. Thus, the strivings for security and for instinctual gratification are characteristically combined in the impulsive action. Running away, kleptomania, pyromania, gambling, drug addiction, and alcoholism are well known examples of "irresistible" impulsive activities.

The Psychoanalytic Theory of Psychosis

Early concepts (1893–1923). The most important finding to emerge from the psychoanalytic clinical investigations of the neuroses was the existence of an unconscious mental life

and the description of its effects on conscious thought, symptoms, and behavior. On the basis of these data, Freud was able to demonstrate that the biological concept of adaptation was valid for all mental disorders. This concept led, in turn, to Freud's insight into the purposefulness of a psychosis. He suggested that psychosis might best be understood as the patient's mode of adapting to his emotional and realistic needs, to his physical health and intelligence, and to the environmental stresses with which he is confronted. Freud offered clinical evidence in support of this hypothesis by demonstrating that a definite psychotic symptom, hallucination, served a useful purpose.

In a broader frame of reference, Freud's greatest contribution to the psychology of psychosis came from his study of dreams. He pointed out that both the dream and psychotic thought were representative of a primitive type of thinking, characteristic of infancy and of the animistic stage of development which antedates mental differentiation of autistic and objective experiences. This application of the investigation of dreams to schizophrenic thought was elaborated on in detail by Carl Jung, and his formulations enabled other workers to demonstrate the validity of this basic concept, i.e., that delusions and hallucinations, like dreams, are prelogical forms of thinking. For example, in his paper on "The Influencing Machine," Viktor Tausk described a schizophrenic patient's delusion that he was magically influenced by a machine, and he showed that it derived from genital sensations.

Studies of paranoia. Understanding of the mental symptoms of paranoia was greatly facilitated by discovery of the existence of unconscious homosexuality and the mechanism of projection. Freud's theoretical formulations concerning this form of psychopathology were, of course, based on his clinical experience. In addition, however, he acquired considerable insight into its genesis as a result of his careful analysis of the autobiography of a patient (Schreber) who had recently recovered from a severe attack of paranoia, and whom Freud had never seen.

In brief, Freud postulated that in paranoia the need to project coincided with an unconscious need for homosexual love which, though of overwhelming intensity, was consciously denied by the patient. He also suggested that paranoid delusions represented sexual conflicts concerning persons of the same sex, which had been projected onto some other person or force, which was then perceived as persecuting.

Other workers emphasized the close relationship of paranoid symptoms to infantile fantasies, in which feces are personalized and considered animistically as dangerous beings which threaten the individual. In this connection, the relationship between paranoia and a stage of development at which the emotions are centered on a particular part of the object's body, rather than the total person, was demonstrated by Abraham. Abraham also noted that paranoid psychosis resembles certain phases of melancholia, in that the patient's fantasies indicate a desire to incorporate the object. However, paranoid psychosis differs from melancholia in that in paranoia the hostility is directed against a part of the object rather than the whole and also in the prominence of fantasies that this incorporated part object can be destroyed and eliminated by defecation. The concurrent demonstra-

tion of the relationship of very primitive fantasies of aggression to overwhelming anxiety and the need to project has facilitated further understanding of this clinical entity. One question remained open, however: the reason why the homosexuality of paranoid patients had become so intense and was so intolerable was not investigated by Freud or his co-workers.

The role of narcissism in psychosis. In his paper, "On Narcissism," Freud stated that psychosis was characterized by the patient's incapacity for normal emotional interest in other people and things. He did not agree that the psychotic process represents a total depletion of libido; rather, it involves a redistribution of those proportions of libido normally devoted to object love and self-love. The energy withdrawn from impoverished love relationships produces an abnormally excessive interest in the bodily functions and psychic attributes of the self. Concomitantly, the psychotic patient's use of language indicates an emotional interest in the verbal symbol, rather than the object the word represents. Many of the more obvious symptoms of psychosis are secondary to this primary loss of the capacity to love others; indeed, they are very rudimentary and primitive efforts to reestablish an interest in others.

Regression to functioning at an earlier stage of mental development is manifested not only in prelogical ways of thinking, but also in the fact that psychotic patients extract pleasurable experience chiefly from their own sensory experience, without requiring a reciprocal relationship between themselves and another person.

In summary, the conspicuous elements of the clinical picture in most psychotic states consist of fragments of the intact personality and incomplete phases of psychotic regressions, and efforts at restitution. Freud concluded that delusions, hallucinations, and certain forms of disorganized behavior were secondary phenomena which represented rudimentary efforts on the part of the patient to restore his lost feelings for objects.

Current concepts. Subsequent investigations have followed Freud's suggestion that the conflicts which result in psychotic adaptations occur primarily between the individual and his environment. In contrast, in neurosis, the conflicts are primarily within the personality, between unconscious infantile wishes and adult attitudes. Recent work has focused on the detailed analysis of the disturbances and disorganizations in ego functioning which have impaired the patient's relationship with reality. In brief, psychoses are seen as resulting from defects in the ego's integrative capacities; from the ineffectiveness of those functions essential to the capacity for establishing real relations with people for both pleasurable and egoistic reasons; and, finally, from the impairment of those functions essential to the control of intense infantile wishes by normal or neurotic mechanisms. Investigations of the ego's adaptive capacities have

shown that the psychotic, like the neurotic, needs to adapt in a way which will enable him to avoid anxiety. However, the psychotic person's adjustment depends on the more primitive types of defense, which normally predominate before a high degree of personality organization is attained. The most important among these primitive defenses are flight, shown in social withdrawal, and the simple inhibition of impulses, which is very apparent in many psychotic delusions. Obviously, these defense mechanisms are much less highly organized than repression or reaction formation, for example. Again, in contrast to the neurotic, the fear of detection by others, rather than the guilt of later childhood and maturity, is also more conspicuous in the social reactions of the psychotic. Finally, identifications, i.e., the adoption and organization of patterns with elements which were originally perceived as details of other people's behavior, play a very important role in psychosis. These derive from emotional relations and early reactions to other people which have played a conspicuous role in the development of the psychotic patient's ego's capacities.

The development of greater understanding and, perhaps, therapeutic techniques which bear a more specific relationship to etiological factors awaits the accumulation of further knowledge regarding the primitive ego of the child and the phases and mechanisms of its development. Recent studies of the development of the ego's capacity to transform primitive drives into socially useful functions (i.e., sublimation) and of factors which interfere with the development of this crucial ego function have enhanced our understanding of the pathogenesis of psychosis. With respect to treatment, modifications in the free association method have made possible an approach, not hitherto possible, to a variety of psychotic states, and to the problem of vulnerability and predisposition to psychosis. It must be pointed out, however, that many of these initial concepts are still in a state of transition.

Nosology

Hypochondriasis. The "actual neuroses" (the term Freud used to describe neurasthenia and anxiety neurosis) have ceased to be a significant part of psychoanalytic nosology. In fact, these clinical syndromes can be recognized as phases of ego regression or phases in the return to optimum ego functioning, yet they are referred to only rarely in the literature. Hypochondriasis, which Freud included among the "actual neuroses" originally, and the pathoneuroses may well be indicative, at least in certain instances, of phases of disorganization and reorganization of integrated ego functioning; the consensus of psychoanalytic opinion on this issue has not been determined. It is recognized, however, that hypochondriasis is an organ neurosis, although the physiological factor involved is still unknown. It may be assumed that certain psychogenic factors, e.g., a state of dammed up libido or anxiety

to which the individual responds with narcissistic withdrawal, create organic changes which, in turn, give rise to hypochondriacal sensations. Hypochondriasis rarely appears as an isolated neurosis; more frequently, it appears to complicate the picture of some other psychopathological condition, such as compulsion neurosis or depression, or it appears as a stage in the development of or recovery from psychosis. Sadistic and hostile impulses withdrawn from objects and represented in the form of organic complaints may play a particularly pronounced role in hypochondriacal syndromes. The typical hypochondriac is a conspicuously narcissistic, seclusive, monomaniacal person, often in a transitional state between reactions of a hysterical character and those which are delusional and clearly psychotic. It is hoped that further psychoanalytic study of infantile development will contribute to our understanding of these frequently encountered clinical states.

Melancholia. Initial insights into the internal origins of various forms of affective regressive states were advanced by Freud as early as 1915. In his paper on "Mourning and Melancholia," Freud emphasized the topographical regions and systems of the psychic apparatus which were involved in melancholic states, the regression of the libido, and the abandonment of the unconscious cathexis of objects. Freud's views differed in this respect from those of Abraham, who also stressed the importance of anal-sadism and maintained that its role in melancholia was comparable to that of anal eroticism in obsessional neurosis. Abraham also pointed out, however, that anal-sadistic impulses contribute to many other clinical syndromes as well. Freud, in turn, emphasized the fact that the pain in mourning was limited to loss of an external object. In contrast, in melancholia the ego itself is impoverished because it has experienced an internal loss. Thus, melancholic depressions may or may not be precipitated by an actual loss. As a concomitant of loss, the melancholic suffers a shattering fall in self-esteem. The ego itself seems poor and empty, and as such it is deserving of reproach by the superego. The early formulations of both Freud and Abraham concerning melancholia and depression emphasized the precipitating frustration in object love, accompanied by flows to narcissistic libido, which reinforced early oedipal disappointment, and early introjection of an ambivalently loved parental image. These concepts are still considered valid.

Depression. Abraham's continued investigations of his own and Freud's propositions within the framework of infantile libidinal development, and particularly in regard to the oral phase, led to further understanding of the mechanisms involved in depression. He suggested that the conflicts of depressed persons centered around oral and anal-sadistic impulses and pointed out that persons who were prone to depression often had a markedly obsessional underlying character.

Pathogenesis. On the basis of these hypotheses, Abraham formulated the concept of "primal depression," to designate severe narcissistic injury which had occurred in early childhood through disappointments in "love." Later, Rado studied the effect of various vicissitudes of the nursing situation on the infantile ego and postulated a relationship between the etiology of depression and oral frustration, on the one hand, and aggression, particularly at the oral level, on the other. More recently, Edith Jacobson has discussed the impact on the young child's ego formation of early disillusion about parental omnipotence, and subsequent devaluation of the parental images. Disillusion and devaluation of the parental images leads to "destruction" of the infantile self-esteem and gives rise to a primary depression which is repeated whenever the adult is similarly disillusioned. Thus, early ambivalent relationships with the parent figures may play a decisive role in the etiology of depression.

Other authors have expanded on this concept: Fenichel ascribed the general predisposition to depression to an "oral fixation, which determines the later reaction to narcissistic shocks" and added that "the narcissistic injury may create a depressive disposition because it occurs early enough to be met by an orally oriented ego," that is, an ego which depends on external oral-narcissistic supplies. Fenichel also discussed the possibility that shocks to the self-esteem in early childhood may secondarily create the decisive oral fixation, in the sense that the ego may become fixated to oral defense mechanisms. Much of the evidence cited by these authors in support of their hypotheses would seem to confirm Melanie Klein's theory that the achievement of a "whole" object relationship is regularly accompanied by anxiety, together with a definite and specific vulnerability to depression in the event of object loss. Zetzel, however, has argued that this view implies a greater incidence of infantile psychosis than actually exists.

The "mechanism" of depression. All persons experience periods of depression in the face of real or fantasied disappointments. However, the orally dependent person, who requires constant narcissistic supplies from outside, is most likely to manifest this reaction in its most severe form. The prototype of depression is the deprivation, suffered by the infantile ego, of vital narcissistic supplies. The availability of such "supplies," in the form of love, affection, and care, is most significant, in terms of future development, at the oral stage.

Later, with the internalization of the parental images, which signifies the passing of the Oedipus complex, the struggle to secure love from the need-satisfying object on an intrapsychic level takes place (i.e., the ego now seeks the approval of the superego). However, the child experienced this subsequently internalized need-satisfying object as frustrating and strict initially, and his attitude toward the object displayed a corresponding hostility. The qual-

ity of this early—and most crucial—object relationship gives the superego a critical and aggressive cast. The severe self-reproaches of depressed persons are another concomitant of the infant's hostility toward the internalized object and also represent the ego's efforts to win the favor of the superego through devaluation of the self. In summary, when early object relationships were defective, early intrapsychic conflicts may be revived. Once the mechanisms described above are set into operation by frustration and loss in adult life, they will give rise to depression.

Symptomatology. The symptom of depression is as ubiquitous as life itself; for it is a natural reaction to those events which must be counted among the normal vicissitudes of life. Consequently, it is the excessive duration and domination of the organism by depressive affect, rather than its occurrence, which is pathological. Both depression and melancholia are characterized by a decrease in self-esteem; a sense of helplessness; the inhibition of ego functions to varying degrees; and a subjective feeling of sadness or loss of varying intensity. It has also been described as a basic affective state in which the ego feels incapable of fulfilling its aims or aspirations, although these aims persist as desired (but "hopeless") goals. Finally, persons prone to depression often display a pseudo independence and self-assurance which, in fact, is a reaction to early severe deprivation and is intended to serve as a defense against future deprivation.

Manic-depressive psychosis. The manic-depressive person manifests a particular kind of infantile narcissistic dependency on his love object. To offset his feelings of unworthiness, he requires a constant supply of love and moral support from a highly valued love object, which may be an individual, or an organization or "cause" which he feels he "belongs to." As long as this object lasts, he will be able to function with enthusiasm and high efficiency. In fact, however, because of his strong self-punitive tendencies, the manic-depressive's object choice is masochistically determined and is bound to disappoint him. Thus, he, himself, sets the stage for his illness. All the ambitions and pursuits of the manic-depressive individual evolve from representations of the overvalued parental love objects, which extend, as it were, to the whole world. Consequently, when he is disappointed by the love object, ego functioning is impaired at every level.

The depressive phase. Often, the depressive phase of manic-depressive psychosis closely resembles paranoia, insofar as the patient's fantasies show a similar desire to incorporate the object. However, paranoia differs from depression in that hostility in the former condition is directed against a part of the object (breasts, penis, buttocks, hair, feces) rather than the whole, and also in the prominence in paranoia of fantasies that this incorporated part object can be symbolically destroyed and eliminated by defecation.

The depressive phase subsides and gives way to temporary elation, i.e., mania, (1) when the narcis-

sistically important goals and objects appear to be within reach once again; (2) when they have become sufficiently modified or reduced to be realistically attainable; (3) when they are renounced completely; or (4) when the ego recovers from its narcissistic shock and regains its self-esteem with the help of various recuperative agencies, with or without a change in object and goal.

The manic phase. Theoretical efforts to grapple with the problem of mania in psychoanalysis have passed through various stages. Initially, mania was approached from the libidinal standpoint; however, more recent studies have stressed the role of the structural components of the psychic apparatus and the importance of object relationships and their inner representations. Since the very purpose of manic flight is to avoid introspection, mania does not lend itself to fruitful psychoanalytic study. It is generally agreed, however, that mania represents a way of avoiding awareness of inner depression and includes denial of painful, inner reality, and flight into external reality; in other words, it is a denial of the sensations of depression by proclaiming specific opposites. Since the manic person does not want to become aware of his own feelings, he cannot permit himself to empathize with others; thus, he is emotionally isolated.

Lewin's work on elation focuses on the oral-libidinal and oral-aggressive elements in mania, which he expands into an oral triad of wishes to eat, to be eaten, and to sleep, all of which are linked up with the infant's experience at the breast. He describes, in structural terms, the fusion of ego and superego (ego-ideal) in elation, and the prominent use of projection, denial, and identification as major defenses. Lewin has also emphasized ego regression as a concomitant of elation, insofar as there is a return to the pleasure principle. Finally, he compares mania to a waking dream; in terms of the economics of elation, the abundance of energy characteristic of this phenomenon represents a concomitant depletion in the energy available for reality testing or coping with superego demands.

The schizophrenias. Psychoanalytic concepts regarding the schizophrenias continue to undergo modification and revision. Originally, Freud postulated that the onset of schizophrenia signified a withdrawal of libido from the outside world; this libido was subsequently absorbed into the ego (megalomania) or returned to the outside world in the form of delusions.

Recent clinical interest in schizophrenia has centered on the intense ambivalence which is characteristic of these patients, their retaliation anxiety, and the infantile ego mechanisms which they typically employ in their relationships with objects and the ultimate failure of which has resulted in the patient's decompensated or regressed state. Two stages are particularly conspicuous in the clinical picture of schizophrenic regression, as emphasized by Freud and

Fenichel: first, the break with reality; second, the attempts to reestablish contact with reality.

Clinical concepts. Object relationships in schizophrenia are based on the wish to possess the parental objects or their substitutes through fusion. Primitive introjective mechanisms, fixation at the early oral stage of libidinal development, and multiple impairment of ego functions have been demonstrated repeatedly. Frustration of basic libidinal needs or factors which weaken ego resiliency, such as physical illness, or increased demands on the patient's love or work capacity may precipitate the acute psychosis.

Poorly warded off homosexual and other pregenital impulses, particularly those of a sadistic and destructive nature, play an important role in schizophrenic regression. With the onset of the psychosis these early sources of libidinal excitation cannot be mastered and flood the ego apparatus. If the libido returns to the ego, a megalomaniac picture will result. If, on the other hand, the sadistic impulses are projected onto the external world, as is the case in paranoid schizophrenic states, the once ambivalently loved person or his representative will be perceived as the persecutor.

Psychophysiological concepts. Several workers have approached severe regressive states from the standpoint of a unified concept of psychophysiological functioning. Such an attempt to conceptualize schizophrenia as a psychophysiological entity has been made by Mann and Semrad. These authors, extending the work of Felix Deutsch, conceive of the conversion process as the pathway which may illuminate the dynamic interrelationship between mind and body. Concomitantly, they attribute schizophrenia to a defect in ego development which, in turn, is the consequence of the early failure of the conversion process to bind excessive instinctual excitation. Individuals vary in the face of severe psychophysiological distress in their capacity to manage or absorb affect through somatic conversion processes. If the capacity of an individual in this regard is exceeded, the need for further defenses arises, and these are then regressively invoked. Thus, the more immature or narcissistic ego defenses that are employed in schizophrenic psychoses are much more "body-oriented" than the more mature defenses. In the narcissistic defenses affect is concentrated upon the self to the marked exclusion of external objects. It is reasonable to assume, then, that the need for these defenses arises in inverse proportion to the success with which the conversion process can absorb affect.

Pathogenesis. Identifications, following the mechanism of "identification with the aggressor," are prominent in schizophrenic psychoses, and such identifications result in character traits which are related to the unconscious perception of the aggressor. In schizophrenia, the aggressor may well be experienced primarily as a foreign body in the patient's ego. The defenses available to the ego at this point in its develop-

ment, i.e., the narcissistic defenses, may also be affected in that they become intensified and specialized so that they emerge as a prominent executant series of patterns, in the form of denial, projection, and distortion. Such prominence seriously compromises the functioning ego in its interpersonal negotiations and eventually assures the frustration of its object needs.

Although the object with which the ego identifies is experienced as an aggressor and perceived as a foreign body, there is some ambivalence in this relationship. In this intense, symbiotic relationship, the object becomes a positive, pleasure-giving source as well. Indeed, these positive pleasurable aspects become the source of narcissistic supply and the major factor in balancing aggression, making it possible for the ego to remain intact. However, this stability is extremely vulnerable; it can be maintained only until such time as the individual loses, realistically or in fantasy, primary satisfying objects and/or, to a lesser extent, secondary substitutes for these objects.

Once this kind of loss has occurred, the previously balanced "poison" of the aggressor is liberated; now the ego is confronted anew with the problem of containing and controlling aggression, while libidinal problems assume a secondary position. We might say that at this point the conversion process has failed; the individual is thrown once more into a disorganizing and exhausting state of exquisite psychophysiological pain and must soon reach toward another solution. The total process may be acute and overwhelming, or it may be slowly regressive. In any event, this explains the fact that, invariably, schizophrenic reactions include distortions of the external world, in the form of a series of frightening, confusing, and distorted body perceptions.

Thus, one may describe the predisposition to psychosis as due to the tenuous and delicate balance between identification with the ego-ideal and identification with the aggressor. This balance is maintained by special ego defenses, by character disorder, or by disorders in psychophysiological functioning which enable symbolic expression of conflict, although the psychophysiological relationships are poorly understood. The special narcissistic defenses used by schizophrenic patients are molded into organized patterns of denial, projection, and distortion. The ego is altered so that it operates in a self-consoling manner; to do so, it must either deny the presence of sensation, deny responsibility for sensation, or lose the ability to distinguish between sensations which emanate from internal or external stimuli. Denial, projection, and distortion are themselves methods for altering sensory perceptions so that they may become ego-syntonic. Specialization of the narcissistic defenses becomes necessary because of the inadequacy of ego-ideal identification, which impairs the ego's capacity for repression and other, more mature defenses to varying degrees.

In summary, most frequently schizophrenic regres-

sion is precipitated by loss and frustration of object needs. Dynamically, the effect of loss results too readily in the supremacy of negative affect, thus dislocating the delicate balance between ego-ideal identification and identification with the aggressor. This inundation with negative feeling necessitates regression to the point of deepest fixation, the narcissistic position, where the patient not only is a potential victim, but also operates for self-consolidation. For only in this position can he achieve tension relief. The path of regression will vary according to whether the losses are acute and overwhelming, or slow and cumulative. It will depend, too, on the individual's structural organization. When the illness is correctly diagnosed, its course can be plotted accurately, and it is possible to demonstrate conclusively, especially in situations of chronic loss, an orderly progression or relinquishing of the more mature defense mechanisms.

Admittedly, the preschizophrenic ego is weak in terms of the development of more mature defense mechanisms. However, with the onset of psychosis, elements of more mature mechanisms which have become established become admixed with infantile patterns. This may account for the clinical confusion surrounding schizophrenias, which demonstrate not only many different kinds of mechanisms, but also various shadings of these mechanisms, giving rise to a confusion of terms, such as schizoaffective component, hysterical component, hypochondriacal component, neurasthenic component, etc.

In general, clinical evidence has shown that the acute onset of schizophrenia is related to increased intensity of the paranoid anxiety, the patient's feelings of omnipotence, and intolerable depressive anxieties, all of which had been previously warded off by narcissistic ego patterns of behavior. In addition, the patient typically demonstrates perceptual distortion, self-hatred, and reliance upon infantile and highly dependent patterns of object relationships.

Classical Psychoanalytic Treatment

The classical psychoanalytic treatment method is described in detail elsewhere in this volume. However, the therapeutic technique which Freud elaborated and which was later expanded by his followers is summarized briefly herein because of its crucial relationship to the evolution of psychoanalytic theory.

Evolution. In essence, modern psychoanalytic treatment procedures differ from those which Freud developed originally in just one fundamental respect. At first, Freud anticipated that recognition by the physician of the patient's unconscious motivations, his communication of this knowledge to the patient, and its comprehension by the patient would, in itself, effect a cure. But further clinical experience demonstrated the fallacy of these expectations. Specifically, he found that his discovery of the patient's unconscious wishes, and his ability to impart his findings to the patient, so that they were accepted and under-

stood, was not sufficient. For while this might permit clarification of the patient's intellectual appraisal of his problems, the emotional tensions for which he sought treatment were not alleviated. This led to a significant breakthrough: Freud now realized that the success of treatment depended on the patient's ability to understand the emotional significance of an experience on an emotional level, and retain that insight. In that event, if the experience recurred, it would elicit another reaction; it would no longer be repressed. And the patient would have undergone a change in his psychic economy.

Freud continually refined his technique, on the basis of his theoretical advances, so that psychoanalysis is now recognized as a specific method for reaching and modifying unconscious phenomena which give rise to conflict. More specifically, in order for a conflict to be considered a neurotic conflict, at least one aspect must be repressed. Psychoanalysis attacks repression and tries to bring repressed material back to consciousness, so that the patient, on the basis of his greater understanding of his needs, motives, etc., may find a realistic solution to his conflict. Freud elaborated a treatment method which attaches minimum importance to the immediate relief of symptoms, moral support from the therapist, or "guidance counseling." The goal of psychoanalysis is to pull the neurosis up by its roots, rather than prune off the top. In order to accomplish this, it is necessary to break down the deep pregenital crystallization of id, ego, and superego and bring the material of conflict near enough to the surface of consciousness so that it can be modified and reevaluated in terms of adult reality. This, above all, distinguishes the classical psychoanalytic treatment from psychotherapy.

The repression of the forces of conflict is accomplished by design, and the patient is unaware of the psychic mechanisms he has employed. By means of this isolation of his "basic" problem, the patient has protected himself from what seems to him to be unbearable suffering. No matter how it may impair his functioning, the neurosis is preferable to the emergence of unacceptable wishes and ideas. All the forces which permitted the original repression are mobilized once again in the analysis as a resistance to this threatened encroachment on dangerous territory. No matter how much the patient may cooperate consciously, and no matter how painful his neurosis may be, he automatically defends himself against the reopening of old wounds with every subtle resource available to him.

Treatment techniques

Free association. The cornerstone of psychoanalytic technique is free association. The patient is taught this method and instructed to use it to the best of his ability throughout the treatment. Occasionally, it is suspended for a rational review of the material elicited, and, indeed, these "intellectual" discussions

are indispensable interruptions. However, by psychoanalytic standards, their function in effecting therapeutic change is quite secondary.

Resistance. The most conscientious efforts on the part of the patient to say everything that comes to mind are never completely successful. Signs of resistance are apparent throughout the course of every analysis. The patient pauses abruptly, corrects himself, makes a slip of the tongue, stammers, remains silent, fidgets with some part of his clothing, asks irrelevant questions, intellectualizes, arrives late for appointments (or finds excuses for not keeping them), offers critical evaluations of the rationale underlying the treatment method, cannot think of anything to say, or censors the thoughts that do occur to him and decides they are banal or irrelevant and not worth mentioning.

The development of resistance in analysis is quite as automatic and independent of the patient's "will" as the development of the transference, and the sources are equally unconscious. However, the emotional forces which give rise to resistance are opposed to those which produce the transference. And, as a result, the analysis becomes a recurring conflict between transference and resistance, manifested by involuntary inhibition of the patient's efforts to freely associate which may last for moments or days. The significance of this conflict for analytic therapy is obvious. It is a repetition of the very same sexuality-guilt conflict which originally produced the neurosis itself. The transference may itself serve as a form of resistance, in that the wish for immediate pleasure in the analysis can circumvent the essential goals of treatment. Thus, the analysis of resistance constitutes the prime function of the analyst; it also accounts for the extended period of time required for psychoanalytic treatment. For, in fact, no matter how skillful the analyst, resistance is never absent (except perhaps in those patients who are seriously ill and would not be "eligible" for classical psychoanalytic treatment in any event).

The role of the analyst. Interpretation is the chief "tool" available to the analyst in his efforts to reduce unconscious resistance. As mentioned earlier, in the early stages in the development of psychoanalytic therapeutic techniques, the sole purpose of interpretation was to inform the patient of his unconscious wishes. Later, it was designed to help the patient understand his resistance to spontaneous and helpful self-awareness. In other words, in current psychoanalytic practice, the analyst's function as interpreter is not limited to "paraphrasing" the patient's verbal reports, but to indicating, at appropriate moments, what he is *not* reporting. Consequently, as a general rule, analytic interpretation does not produce immediate symptomatic relief (beyond the usual "honeymoon period"). On the contrary, there may be a heightening of anxiety and the emergence of further resistance.

In summary, the procedures unique to psychoanalysis help to circumvent resistance. The first of these is the patient's use of free association. The second is the passive role assigned to the analyst in the treatment setting. As described above, free association refers to the spontaneous expression of uncensored thoughts which supplement the patient's efforts to fathom his own mind by direct and logical intellectual thought. Free association is the path to the unconscious. As such, it is central to the classical psychoanalytic method, and the patient's eligibility for treatment depends on his willingness (and ability) to comply with this basic "rule" of treatment. The patient is obligated thereby to express verbally everything that comes to his mind, without selection or reservation. Ordinary rules of conversation, such as adherence to the topic under discussion, orderly presentation, or regard to the social conventions and amenities are abrogated.

The passive role of the analyst implies his avoidance of permissive, as well as authoritative expressions, and allows him to limit himself to interpretations offered at the proper time, of the patient's mental dynamics as these emerge in his free associations and to clarification of the way the patient's ego defense mechanisms operate to preclude free association (and thereby to preclude insight into his unconscious wishes and impulses). In this respect, the passive role of the analyst reduces the realistic features of the patient-physician relationship to a minimum.

If a correct interpretation is given at the proper time, the patient may react either immediately or after a period of emotional struggle during which he offers new associations. These new associations often confirm the validity of the previous interpretation and add significant additional data, disclosing motivations and experiences of the patient which the analyst could not previously have been aware of. Generally speaking, however, it is not so much the analyst's insight into the patient's psychodynamics which produces progress in the analysis. Rather, it is his ability to help the patient to gain this insight for himself, by reducing unconscious resistance to such self-awareness through appropriate, carefully timed interpretation. Psychoanalysis has shown that, at best, the therapeutic benefits produced by the pressure of the analyst's exhortations are only very temporary. The only pressure of lasting therapeutic value derives from the patient's awareness of his own instincts.

The dynamics of the therapeutic process. In the course of his analysis, the patient undergoes two processes, remembering and reliving, which constitute the dynamics of the treatment procedure.

Remembering refers to the gradual extension of consciousness back to early childhood, at which time the core of the neurosis was formed, for this stage of development marked the onset of the interference and distortion of the patient's instinctual life. Consequently, making the unconscious conscious is accom-

plished, in part, by the recovery of important childhood experiences through the patient's actual memory of these events, but more often in other ways, such as fantasy, inference, and analogy. In patients who have been analyzed successfully, this means more than a mere verbal autobiographical reconstruction. Inevitably, inner convictions and values, which were formed early in life, will be reevaluated and altered so that they will contribute to, rather than hinder, the patient's optimal functioning.

Reliving refers to the actual reexperiencing of these events in the analysis itself, in the context of the patient's relationship with the analyst.

The transference. Through free association, hidden patterns of the patient's mental organization, fixated at immature levels, are brought to light, comparatively free from disguise. These free associations refer to events or fantasies which are part of the patient's "private face." When they are shared in the analytic setting, the listener (analyst) is gradually invested with some of the emotion which accompanies them. That is, the patient displaces the feelings he originally directed toward the participants in these early events onto the analyst, who becomes, alternately, a friend or an enemy, one who is nice to him or frustrates his needs and punishes him, one who is loved or hated. Moreover, this tendency persists, so that to an increasing extent the patient's feelings toward the analyst replicate his feelings toward the specific people he is talking about or, more accurately, those his unconscious is "talking about." The special type of object displacement which is an inevitable concomitant of psychoanalytic treatment is called "transference."

As unresolved childhood attitudes emerge and function as fantasy projections toward the analyst, he becomes, for the patient, a phantom, composite figure who represents various important persons in the patient's early environment. Those earlier relationships which remained unresolved are reactivated with some of their original vigor. Gradually, the patient sees himself as he really is, with all his unfulfilled and contradictory needs spread before him. The conscious, scientific use of transference as a dynamic therapeutic force through the analysis of its unconscious sources is unique to classical psychoanalysis.

The combination of these two processes—remembering and reliving—enables the patient to gain deeper insight into the defects in his psychological functioning, in spite of himself.

The transference neurosis. Psychoanalytic treatment may be divided into specific phases. During the introductory phase, the patient becomes familiar with the free association method and the routine aspects of treatment; the ideas and feelings which are characteristic of the individual begin to emerge; and there is an increasing mutual understanding of the patient's assets and the life difficulties which have brought him to treatment.

The "transference neurosis" usually develops during the second phase of analysis. A patient who, at first, was eager for better mental health no longer consistently displays such motivation during treatment hours. Rather, he is engaged in a continuing battle with the analyst, and it becomes apparent that his most compelling reason for continuing his analysis is his desire to attain some kind of emotional satisfaction from the analyst. In other words, at this point in treatment, the transference emotions are more important to the patient than the permanent health he was seeking. It is at this point that the major unresolved, unconscious problems of childhood begin to dominate the patient's behavior. They are now reproduced in the transference with all their pent up emotion. The patient is striving unconsciously to recapture what he was actually deprived of in childhood.

The analytic situation is governed by the three outstanding characteristics of the instinctual life of early childhood: the pleasure principle (prior to effective reality testing), ambivalence, and repetition compulsion. The full comprehension and management of the transference neurosis is a test of skill which sharply differentiates those analysts who have received adequate training in classical psychoanalytic theory and technique from those who have not. One situation after another in the life of the patient is analyzed until the original infantile conflict is revealed. Only then does the transference neurosis begin to subside. Termination of the analysis dates from this time; but, again, it is a gradual process and is never complete with the last visit to the analyst. However, if exposure of the unconscious source of the patient's major problems was fairly thorough, thereafter, at times of emotional crisis, the patient can resolve, through association and without assistance, those areas of conflict which were not entirely worked through with the analyst. After a variable period, the temporarily accentuated awareness of the unconscious diminishes; useful repressions are partially reestablished; the former patient has less need of introspection; and he is able to deal with life on a more mature and satisfactory basis than was possible previously.

Modification in technique. There is no short cut; psychoanalytic treatment typically extends over a period of years and requires interminable patience on the part of both the physician and the patient. The classical analytic method, which, on the one hand, best serves the aims of therapy, also constitutes the best experimental situation yet devised for studying the more complex features of human nature. However, rigid adherence at all times to the fundamental mechanistic principles of psychoanalytic technique is impossible. For example, the immediate environmental situation may be so serious that the analyst must pay common sense attention to its practical implications. Those patients whose early childhood was extraordinarily deficient in love and affection must be given more praise and encouragement than is advo-

cated by strict analytic technique. Very narcissistic patients and borderline psychotics must establish strong personal feeling for the analyst before they can develop sufficient interest and motivation for treatment. At the same time, however, clinical evidence has demonstrated conclusively that every deviation from strict technique which such special conditions compel prolongs the length of treatment and increases its difficulties considerably.

The results of treatment. The therapeutic effectiveness of psychoanalysis presents problems of demonstration. Impartial and objective critics are handicapped in their appraisals by the fact that so many patients state that they have been "analyzed" when no such procedure was undertaken, or when it was undertaken by someone who exploited the use of the title "analyst," and who, in fact, had no understanding of the science and technique of analysis. Other patients remained in analysis only a very short time and then discontinued treatment themselves or were advised that they were not suitable candidates for such treatment. In any event, except for psychoanalysts themselves, professionals, as well as laymen, demonstrate varying degrees of confusion as to what psychoanalysis is and what it is not.

To begin with, no analyst can ever eliminate all the personality defects and neurotic factors in a single patient, no matter how thorough the treatment. On the other hand, mitigation of the rigors of a punitive superego is an essential criterion of the effectiveness of treatment. Psychoanalysts do not usually regard alleviation of symptoms as the most significant datum in evaluating therapeutic change. The absence of recurrence of the illness or of further need for psychotherapy is a more important index of the value of analysis. However, the chief basis of evaluation remains the patient's general adjustment to life—his capacity for attaining reasonable happiness, for contributing to the happiness of others, and his ability to deal adequately with the normal vicissitudes of life. More specific criteria of the effectiveness of treatment include reduction of the patient's unconscious, neurotic need for suffering; of neurotic inhibition; and of infantile dependency needs; and, on the other hand, an increased capacity for responsibility; for success in marriage, social friendships, and work; and for pleasurable sublimation and recreation relative to his potentialities. The most important criterion of the success of treatment is the release of the patient's normal potentiality which had been blocked by the basic neurosis for further development and maturation.

Indications and contraindications. Psychoanalysis is not the treatment of choice for all forms of mental disorder. It has proven most effective in the "common" psychoneuroses, in which definite symptoms predominate and motivate the patient to seek medical or psychiatric help. These include cases of conversion hysteria (including "classic hysteria"),

phobias without psychosis ("anxiety hysteria"), obsessive and compulsive neuroses, and neurotic depression.

Conversion hysteria. Conversion hysteria, which usually occurs in women, is characterized by bodily symptoms which resemble those of physical disease (e.g., paralysis, anesthesia, blindness, convulsions, pathological blushing, fainting, headaches and other types of pain), but which have no somatic basis. Unless these symptoms occur in very mild form, in an otherwise well adjusted personality, they are positive indications for analysis. The typical course of treatment in such cases is the early alleviation of symptoms and the recognition of basic conflicts produced by genital wishes. Analysis of these conflicts usually leads to fundamental changes in personality, in addition to permanent symptomatic relief. But a minority of cases of hysteria are very difficult to analyze or may even be unanalyzable. This applies particularly to cases of hysteria in women whose personalities are exceptionally infantile, and some chronic cases in which the pleasure derived over a period of years from "secondary gains" is too great to be renounced.

Phobias. Phobias (anxiety hysteria) produce a variety of symptoms in people whose personalities and conflicts are very like those of patients with conversion hysterias. Indications for the treatment of both these clinical entities are similar.

Obsessive-compulsive neuroses. This form of neurosis is more common in men. Treatment is usually much more difficult and protracted than treatment of other neuroses, and, not infrequently, such patients do not derive full benefits from analysis. On the other hand, however, these patients present serious disturbances in total adjustment, so that extended treatment is usually justified, even though the "cure" would not be considered complete by psychoanalytic standards.

Neurotic depression. This syndrome is well understood and often much helped by analytic treatment.

Other symptomatic neuroses. Overt sexual symptoms, such as impotence based on psychic factors, or impaired capacity for mature sexual love, usually represent the repression of fundamental conflicts in early object relationships and are usually permanently relieved through analysis. However, other symptomatic psychoneuroses, such as adult enuresis, tics, and stammering, may be much more resistant to modification. Yet, such symptoms are usually definite indications for psychoanalytic treatment; and treatment generally produces important alterations in basic personality problems, even though the chronically established abnormal muscle habits are not entirely cured.

Homosexuality. Sexual perversions often tend to be quite intractable, and the results achieved in the psychoanalytic treatment of overt homosexuality have been equally disappointing, on the whole. Thus, the indications for psychoanalytic treatment of pa-

tients whose homosexuality is accompanied by psychoneurotic difficulties are much the same as they would be for neurotics who are heterosexual, and the results of treatment, with respect to the neurotic symptoms of the homosexual patient, are quite similar. Alteration of an erotic preference for one's own sex is by no means assured. The more indications there are, either conscious or repressed, of some heterosexual interest in the past history of the individual, and the less completely he has adopted the psychological traits and habits of the other sex, the better is the patient's prognosis.

Psychoneurotic character problems. These clinical phenomena are closely allied to hysteria and the obsessive-compulsive neurosis in etiology and prognosis. Both hysterical and obsessive-compulsive characters display a variety of traits of definitely neurotic origin. When these are a conspicuous and persistent source of tribulation for the patient and the people in his environment, they constitute positive indications for psychoanalysis. A few of the more common of these traits are uncontrollable temper; chronic nagging and constant complaints about others or oneself; excessive diffidence or feelings of inferiority, an inclination to change one's occupation constantly, and repeated unsolved work problems; a succession of unhappy love affairs; an inability to concentrate at work or to finish a job; an inability to derive pleasure from recreation or avocation; and an inability to form friendships. Particularly common in such cases are complaints of marital discord, which is either the result of a neurotic choice of partner, or a neurotic reaction to a maturely selected spouse.

Today, neurotic character disorders are far more common than clear cut symptomatic neuroses, and these patients comprise a large portion of the population for whom analysis is recommended. Narcissistic characters are helped greatly, and even "transformed" by analysis, but the therapeutic prognosis is extremely variable. The more evidence there is of the presence of problems which are definitely psychoneurotic, in combination with narcissistic traits, the more favorable the prognosis for such patients. On the other hand, the prognosis is especially poor for analitic personalities who are very unassertive and readily accept entirely dependent and passive relationships. Mild schizoid characters may be helped by analysis, but they should never be treated by analysts who lack general psychiatric experience; this applies to paranoid characters as well. More serious psychological disturbances, such as alcoholism, drug addiction, psychopathic personality, and criminality, have been helped occasionally by analysis. But, too often, the benefits from therapy are limited because the infantile demands of these patients are almost unbelievably excessive. In fact, their ego functions are seriously impaired in that their sense of reality is defective; they lack the capacity to tolerate frustration and other tensions.

Classical psychoanalysis is a completely appropriate treatment method for the neuroses. Moreover, it can produce a far more complete and fundamental reorganization of the neurotic personality than any other psychotherapeutic technique currently in existence. On the other hand, this unqualified endorsement pertains only to the neuroses. In other forms of psychopathology, the usefulness of psychoanalysis as a treatment method is limited, depending on the extent and strategic location of neurotic elements in these conditions.

Psychosomatic illness. Certain organic illnesses ("reversible" somatic symptoms) are so common an accompaniment of psychoneurosis that cures incidental to the major problems of a neurosis are a common experience of practicing analysts. Chronic and intermittent constipation, anorexia, and other minor ailments of the digestive tract are regularly relieved as a secondary consequence of the analysis of personality problems. The alleviation of a variety of menstrual disorders, and sometimes of sterility of long duration, as a concomitant of the resolution of emotional conflicts surrounding female sexuality is common. Analysis frequently has a therapeutic effect on a variety of other common complaints as well, such as constant colds, headaches, insomnia, pseudo pregnancy, frequency of urination, and skin eruptions. The effect of psychoanalysis on asthma, thyroid disease, disturbances of stomach and intestine, and some skin diseases varies considerably from case to case. Possible reversibility of psychosomatic disease is a major consideration. If the disease process is irreversible, psychoanalysis may still be recommended with the aim of trying to slow the destructive process. However, the somatic process may be not only irreversible, but also impossible to halt. In such cases the misery produced by the somatic disease and the social incapacitation have become the major problems, and the original neurosis is of secondary significance.

Psychoanalytic treatment of psychosis. The effectiveness of analytic treatment of psychosis must be discussed with still less certainty. Classical psychoanalysis is clearly contraindicated. However, there is no question that skillful and prolonged psychotherapy can ameliorate or even permanently remove the more morbid features in some cases. But the question is still open as to whether psychoanalytic technique is as specifically indicated for the treatment of schizophrenia as it is for the psychoneuroses. Moreover, in general, paranoid psychosis is even less amenable to analytic therapy than many cases of schizophrenia (although in those cases where the paranoid process absorbs only a limited portion of the patient's intellectual and emotional life, the prognosis is considerably better).

Eligibility for treatment. The capacity for mature adjustment may be very limited in some individuals, even though they may not have a particularly severe

neurosis. Nevertheless, evaluation of their personalities indicates that no aspect of their functioning is really adult. Nor is there evidence of a strong drive to combat these infantile aspects.

Analysis is contraindicated in extreme cases of this kind, for no element of the personality will strive to utilize the treatment for eventual maturity; the patient will continue to regard the analytic session as an enjoyable hour during which he has someone's exclusive attention just as long as the analyst will put up with it. The psychoanalyst does not regard the secondary gain as the primary rationale for classical psychoanalytic treatment, but as an important obstacle to be circumvented in his work. Not infrequently, however, the secondary gain is so great as to seriously impede or entirely preclude successful analysis; in such instances, the patient has learned to derive so much satisfaction from these secondary gains that the advantages of illness outweigh his suffering.

During treatment, the patient must continue to derive some gratification from life, even though these gratifications may perpetuate his neurotic patterns. Sometimes, relationships which were conspicuous consequences of the neurosis cannot be renounced, even after the patient no longer requires the infantile gratification (and the suffering) they afford. No individual is a self-sufficient unit; his repressed impulses, as well as his mature emotions, constantly mingle with, stimulate, and respond to those of others. The infantile sadism of one partner responds to the infantile masochism of the other and demands it of him, despite the fact that after analysis, the masochist desires a more mature relationship, unconsciously as well as consciously. In other instances, however, analytic results have a favorable effect on the neurotic problems of the patient's spouse as well as on those of the patient, and there is a mutual improvement in marital adjustment.

Specific criteria. Several factors must be kept in mind in judging an individual's eligibility for psychoanalysis. Apart from the capacity for logical thought and a certain degree of ego strength, fundamental vigor of personality is a prerequisite. The analytic patient undergoes a difficult experience. From time to time, he must be able to accept a temporary increase in unhappiness, in the expectation of eventual benefits. The capacity to undergo such stress is an excellent indication of a person's capacity to face the real vicissitudes of life after analysis. When there is some question as to the patient's "qualification" in this regard, a short period of "trial analysis" in order to appraise the problems and potentialities of the patient more completely may be recommended. A youthful mind (either in terms of actual years, or a certain elasticity of functioning) is essential. Chronologic age is a rough measure of total life experience; the more mature a person's experience is, the more apt he will be to utilize the analysis. In general, however, treat-

ment will proceed more quickly to an effective result when patients are in their twenties and thirties. But it is also recommended in adolescence and middle age. The capacity to fight the neurosis is as great an asset in psychoanalysis as it is in life crises, and it varies as greatly among individuals, as does the degree of neurosis itself.

Finally, honest skepticism concerning analysis is usually a good prognostic sign, if it is not so extreme as to prevent the patient from making a determined effort to utilize the unique advantages this method offers. On the other hand, a naive, exuberant conviction at the beginning of treatment that the omnipotent analyst will point the way to an existence which will remain untroubled forever after, that analysis offers a magic formula which will automatically (and painlessly) "make everything right," forebodes very special difficulties after treatment is underway.

Chapter 7

Cultural and Interpersonal Psychoanalytic Theories

7.1 ALFRED ADLER

HELENE PAPANEEK, M.D.

Introduction

(In Alfred Adler's first publication,) a pamphlet issued when he was 28, on the health hazards of tailors, he described two concepts which remained basic to all his later teachings. The first of these concerned the relationship of the individual to his social environment. The second focused on the interrelatedness of body and mind, i.e., the holistic approach. The expression of these two key ideas indicated Adler's awareness of the existence—and importance—of psychological components in all physical disease.

Relationship with Freud

Areas of agreement. Adler read Freud's *Interpretation of Dreams* with great interest and was invited to join Freud's weekly discussion circle in 1902. For a period of 9 years thereafter, Adler was Freud's co-worker, but his role was that of critic, rather than disciple. In 1907, he published his *Study of Organ Inferiority*, which received Freud's enthusiastic endorsement, and in 1910, Adler became president of the Vienna Psychoanalytic Society and co-editor of the *Zentralblatt für Psychoanalyse*. It is quite fascinating to observe how the thinking of Freud and Adler developed, based on their common interest in neurosis and psychosis. They were in agreement that the meaning of neurotic and psychotic symptoms must be understood by the physician; that the physician's knowledge of the patient's experiences in early childhood and his dreams might help to clarify the hidden meaning of these symptoms; and, finally, that the patient's understanding of the connection between these early experiences, on the one hand, and current dream content and symptomatology, on the other, could result in significant improvement, or cure, of his mental illness.

Dissension. Fundamental differences in the thinking of Adler and Freud began to emerge in 1908. Initially, these differences stemmed from Freud's focus on the pathogenesis of neurotic symptoms, as opposed to Adler's interest in their final goal, their purpose. In other words, in contrast to Freud's emphasis on causal explanation, Adler's basic orientation was finalistic and teleological. In a series of heated debates, each man tried to win the other over to his point of view, but the breach grew wider. The final break occurred in 1911 when Adler developed his own theory of personality, in which he redefined the unconscious and challenged the validity of Freud's concepts of basic drives and the phenomenon of repression as an essential prerequisite for the development of neurotic symptoms. Shortly thereafter, he left Freud's circle, together with eight colleagues, to establish the Society for Free Psychoanalytic Research. In 1912, Adler coined the term "individual psychology" to describe his school of thought, and in the same year he published *The Nervous Character*, which summarized his main concepts.

Basic orientation. The Ansbachers have organized and presented Adler's main contributions and theoretical hypotheses in several books and articles. Heinz Ansbacher, in his introduction to the recent edition of Adler's *Problems of Neurosis*, has evaluated the significance of Adler's work as follows:

Freud was revolutionary for his day in that he listened to every word of his patients, knowing that this would be valuable basic information for solving the puzzle of mental disorder. But he was scientifically conservative in that he firmly believed that the patient's inner psychological world was ultimately determined by objective causes that rested in his past. It was scientifically more revolutionary to proclaim, as did Adler, that the inner psychological world of the individual, which had such far-reaching consequences, was not objectively caused, but was ultimately the individual's own creation, and that the individual's course of life received its direction not from relatively objective drives, but from his highly subjective goals and values. And it was more difficult to accept [the fact] that the individual could be quite unaware of the goals and values which he himself had created or accepted than that he was the pawn of an unconscious which supposedly controlled his conscious self.

Theory of Personality

Adler's basic concepts concerning personality development may be summarized as follows.

Unity of the individual. Adler was the first theoretician to describe man as an organic purposeful system with the goal of self-realization and social survival. Thus, the unity of personality is emphasized from both an objective and a subjective viewpoint.) Theories which try to explain psychological processes objectively, as independent entities, or in the form of dichotomized categories, may be satisfying in their orderliness. In fact, however, they are limiting and artificial and do an injustice to the complexities and interrelatedness of life. (The individual (*in-dividuum* = indivisible) and his behavior must be understood as the result of interwoven, dynamic, somatic, psychological, and social processes. We have a need to perceive ourselves as a unit subjectively as well. This sense of unity and continuity is the basis for our sense of identity, for self-esteem and self-acceptance. This theory of the unity of self was developed further in Adler's concepts of life style and life goal,) described below.

Adler's concepts in relation to compensation are part and parcel of this holistic approach, which stresses the unity of mind and body, and their mutual influence on each other.) Useful illustrations of these formulations can be found in Kurt Goldstein's descriptions of the compensatory devices employed by brain-injured patients. For example, Goldstein observed that certain patients, after they have sustained an injury to the brain, never regain adequate functions, to any appreciable degree. Yet other patients with brain lesions which are similar, or even more extensive, are able to achieve an amazingly good adjustment to society. In brief, the patient's progress will depend on his premorbid personality and on his desire to recover.

Unified concept of motivation. The helplessness of the infant gives rise to universal feelings of inferiority which supply the motivation for a compensatory striving for superiority. The term "inferiority complex" describing real or imagined social, physical, or psychological inadequacies stems from this concept. Consequently, the dynamic force behind all human activity is the striving toward superiority, perfection, and totality.) The child wants to overcome his smallness and dependency in his desire for security, mastery, and self-esteem. This striving for self-realization is an integral aspect of life, just as is physical maturation.

Self-determination and life goal. The striving for superiority and success is subjective, in that it is based on man's awareness of himself, on his ability to remember past experiences and to project himself into the future. The individual's life goal is determined by his inventive and creative power; it is an expression of his uniqueness. Each individual develops his concept of self, and of the people and things

which surround him in his own unique, personal way. And his perception of objective realities will influence the formation of his future subjective goals.)

The specific kind of superiority the individual wants to attain and the methods he adopts toward its achievement derive from the particular circumstances of his own life, particularly his biological endowment and his early environment. Out of these biological and environmental factors, the adult has created the "fiction" of a self-ideal. He is only dimly aware of what he is striving for, in an effort to preserve his identity and maintain his self-esteem.

Adler's theory has been criticized for "over-simplification," or "reductionism," on the grounds that he "reduces" all sources of motivation to "feelings of inferiority" and the "striving for superiority." But these terms were used by Adler in a very broad sense. As can be seen from a study of his original writings, the concept of inferiority includes insecurity and anxiety. The striving for superiority implies the adult's search for meaningfulness, for the significance of life; it is the striving for perfection and completion.) Striving for superiority as the goal of life is specific and different for each individual. His subjective interpretation of the past and present will determine his ideas of the future; or, expressed differently, traces of the subjective past, present, and future are present in the individual's phenomenological field.

Life style. Adler's phenomenological explanation of personality development centers on the concept of life style. Life style is defined as the individual's active adaptation to the social milieu, which develops as a unique, personal product of his need for integration into that social milieu and for differentiation from it. The growing child selects from among his experiences, and especially from his own interactions within his family and his observations of their social relations with others, events which can fit into a consistent, coherent pattern. If he is to function effectively in life, order must emerge from confusion. Events which do not fit into a coherent pattern are considered unimportant and are forgotten. Concomitantly, we are unaware of thoughts and feelings which would painfully contradict our self-concept. Thus, Adler was convinced that conscious and unconscious processes are not in conflict but represent dual aspects of a unified relational system.)

Recent research on early infantile development has confirmed Adler's ideas on the earliest phases of development of the self in the infant's social interaction with his first immediate human environment, his mother. Charlotte Bühler has detected the "rudimentary beginnings of self-awareness" in the infant at the age of about 10 months, and she believes that identity as a self-perception occurs simultaneously with the perception of the other person (i.e., the mother) as a person.

(The life style develops in a step-by-step maturation.)

tional process. Children concentrate on and seem singularly preoccupied with the behavior of the adults who surround them. The nonverbal and verbal responses of these significant adults are observed, interpreted, integrated, and remembered—digested and assimilated might be an appropriate analogy. Escalona, in her detailed observations of infantile behavior, has said that a milestone in the course of personality development is the realization by the infant that his behavior, directed toward a person or object in the outer world, has elicited a response. These myriad, repeated, primary experiences constitute the minute pieces of the mosaic created by the child in the first 5 years of his life to form a relatively stable scheme of apperceptions. This individual, creative, goal-directed structuring of memory, perception, and cognition is the basis for the person's life style. The creative interpretation given to our experiences in childhood, the meaning we find in them, makes for mature freedom of choice and self-determination in later life.

A Social context and social feeling. Just as the partial functions of the individual must be understood within the context of the unity of personality, so the total person must be considered within the broader context of society. Adler's distrust of fixed and separate categories, of artificial entities, of dichotomized thinking, is again illustrated by the apparent contradiction between the name he chose for his theory, individual psychology, and his emphasis on the importance of the social milieu in which man functions. Both components, i.e., the individual (a lower system, less open, an indivisible entity) and society (a higher, more open system) are of equal importance in Adler's theory. Adler repeatedly emphasized the fact that individual psychology views and examines the individual within the framework of his social milieu, as a member of society; that the individual cannot be considered in isolation.

In fact, even the child sees himself as dependent on, and embedded in, a social situation or milieu. The infant develops his innate potentiality for social feeling as a by-product of the relationship between mother and child and their need for each other. And the educability of the child derives from growing social interest. Reason and intelligence develop with and through human interaction. If the child grows up under favorable circumstances, his early self-interest will be transformed into the desire for a socially meaningful life, and this goal will be attained in accordance with social reality. Adler conceptualized social feeling as a criterion for mental health: since man's greatest fears concern social isolation and vulnerability of the self through loss of self-esteem, a healthy life style is directed toward achieving competence and social success by working toward the goal of social usefulness. Perhaps Jules Masserman was expressing a similar idea when he spoke of man's ur-defenses against anxiety and dis-

integration; when he described feelings of mastery, of invulnerability of the self, and the conviction of man's kindness to man as "faiths necessary to mankind." Adler also pointed out that increased social feeling enhances man's intelligence, heightens his self-esteem, and enables him to adjust to unexpected misfortunes. When the individual experiences himself not in helpless and frightening isolation but as a useful and contributing member of the community, he shares with others common ethical and esthetic standards and ideals.

Theory of Psychopathology

Whether Adlerian theory is explaining normal or abnormal personality development, its concepts blend to form an integrated whole, and each concept can best be described in terms of its relation to all the others. Accordingly, the following brief account of Adler's theory of the etiology of neurosis and psychosis, their manifestations and dynamics, will be presented within the framework of the basic assumptions of individual psychology concerning normal development. These include the concept of a unique, self-consistent, active, and creative self (style of life); an open, dynamic system of motivation (the striving for a subjectively conceived goal); and an innate potentiality for social living (social interest).

Etiology of neurosis. A neurotic disposition stems from childhood experiences which are characterized either by over-protection or neglect, or by a confusing, alternating mixture of both. Out of these experiences, the growing child creates a negative self-image of helplessness, a conviction of his inability to develop mastery or to cope with the tasks of life. This distorted image of the helpless self is supplemented by his apperception of a social environment which is overtly hostile, punishing, and depriving, or subtly demanding and frustrating.

Thus, these early experiences provide misleading cues, which prevent the child from constructing an apperceptive scheme, a cognitive map, which is adapted to the tasks of social life. Instead of providing encouragement to engage in further efforts toward mastery and achievement, these experiences leave the child fearful and discouraged. Instead of experiencing the pleasures of trusting and loving relationships, the child becomes distrustful or manipulative. He develops a neurotic striving for superiority, to compensate for his exaggerated feelings of insecurity and anxiety. And his vulnerable self-esteem is buttressed by various forms of behavior. In brief, self-protection becomes his primary objective. Moreover, his self-centeredness and his uncooperative struggle for personal superiority to compensate for his exaggerated feelings of insecurity are substituted for the socially directed goal of a meaningful and useful life. Accordingly, problems are solved in a self-centered "private sense," rather than a task-centered "common sense" fashion.

Dynamics of neurosis. The neurotic individual cannot cope with problems or enjoy social life because, as a child, he interpreted and integrated his experiences so that they might serve a protective function, rather than provide adequate building stones for orientation and identity. Once his cognitive organization, his "private map," or inner psychological world has developed, it is difficult for such an individual to give up even the smallest segment of his distorted subjective creation. All the pieces fit together, and any change would disrupt the only adaptive pattern the individual has been able to construct from what appeared to be the crucial cues in his early environment.

In contrast, a life goal which is shaped positively by the child's healthy experience of growing mastery and achievement by the development of his potential capacities for learning, for creativity, and, above all, for the pleasures of social relatedness and love, will result in a flexible life style in which there is no fear of trial and error or of new experiences. Integration of these, correction of previous cognitive errors, and the learning of new patterns continue throughout the individual's lifetime. If, in essence, the life goal is shaped negatively, by fear and anxieties, by the need for protection and safety, then the individual's subjectivity becomes distorted, and his lack of awareness of objective reality serves to maintain a shaky and constantly threatened self-image. Lack of awareness is pathological, if and when the individual develops perceptual and conceptual constancies, or opinions, about himself and the world, based upon previous experiences which he wrongly assumes to have general validity. These faulty assumptions remain uncorrected, first, because he is afraid of facing new, corrective experiences. Second, he lacks "common sense"; that is, he avoids human contact which might clarify these distortions.

In many case histories and clinical examples, Adler elaborated on the "private logic" of such individuals as the neurotic, the psychotic, the criminal, and the addict. Private logic lacks reason or common sense. It is the basis for the formulation of a personal goal, as a product of the individual's misguided conflict with society, "on the useless side of life." "Common sense," on the other hand, is the basis for an essentially cooperative harmony between individual and society, and an innate potentiality for social living.

Diagnostic classification. Adlerian theory has always stressed the idiographic aspects of clinical observation, on the premise that rules and generalizations may become an obstacle to the understanding of the patient's creative potential. (Observation and description of the unique individual are, therefore, considered more important than diagnostic categories and classifications. For teaching purposes, however, Adler described four personality types. The first three—"the ruling," "the getting," and "the avoiding"—all lack social feeling and are unprepared to solve

life's problems. They differ only in the degree to which these characteristics are manifested. In contrast, the fourth type, "the healthy and socially useful person," is actively cooperative with and contributes meaningfully to society. From his cooperation and contribution, he derives feelings of usefulness and fulfillment.

Adler considered compulsion neurosis to be the prototype of all neuroses. In many case histories, he described the indecision and doubt, the striving for "god likeness," the depreciation of others, and the pedantic striving for accuracy as "safeguarding" or protective devices which are used by the neurotic individual in his attempt to attain a goal of personal superiority. While normal psychic life always involves "movement"—from one problem to another, from indecision to choice and decision, from conflict to solution in a variety of significant and useful styles—neurotic conflict is perpetuated by an evasion of these tasks.

Theory of psychosis. From Adler's viewpoint, psychosis, whether schizophrenic or manic-depressive, was due to a combination of somatic and psychological etiological factors. Importance is placed on understanding the psychotic's private logic, recognizing its coherence in either grandiose or depressing fantasies, despite a lack of "reason" or common sense.

Adler also pointed out that, while the neurotic may suffer from a sense of failure, whether real or imagined, the psychotic does not accept the ultimate criterion of social validity, and his fantasies compensate for his sense of utter hopelessness and despair of ever achieving significance in the real world.

Treatment

Child guidance. As mentioned earlier, Adler was convinced that the experiences in early life are the first training and testing ground in social behavior. The mother-child relationship is of crucial importance, and emotional closeness during infancy and early childhood provide the most intensive and immediate experience of love and fellowship that the child will ever have. Ideally, this love and dependency will pave the way for the child's optimistic, trusting, and responsible attitude toward people and society. Nursery school, kindergarten, and elementary school, with their opportunities for companionship and friendship, continue his training in social feeling and provide a testing ground for self-assertion and interaction.

Although he was aware of the multiple factors that contribute to the ultimate personality, Adler also emphasized the influence of the "family constellation," that is, the totality of interactions among all the members of the family, and, in particular, the significance of the child's ordinal position in relation to his siblings. In brief, Adler's theoretical approach permeated every facet of the child's growing

personality and, in addition, included a therapeutic concern for "the problem child," which focused on child guidance and education.)

The ideas outlined by Adler in this connection played a crucial role in the decision to organize child guidance clinics in Vienna at the beginning of this century; in a broader sense, they also influenced the organization of the Austrian school system and its educational "philosophy." More specifically, Adler maintained that close cooperation between family and school was an important principle in the treatment of disturbed youngsters. (Not only the child, but also his family and teachers were interviewed and counseled with various professionals present. These techniques were especially helpful in alleviating the child's feeling of isolation; in clarifying for the patient, for his siblings, and for the adults in his immediate environment, the interaction among all the people involved and the impact each had on the other.) An atmosphere of optimism prevailed, which derived from the knowledge that others had experienced and solved similar problems, and this optimism was reinforced by attitudes of helpfulness and acceptance. All of Adler's methods—diagnostic exploration of the child's familial and educational situation by questionnaires; family interviews and family treatment; the combined efforts of a "therapeutic team," consisting of a counselor, parents, teachers, truant officers (if necessary), and other representatives of society—are still in use in child guidance clinics in both Europe and this country.

Psychotherapy. Adler conceived of psychotherapy as an attempt to mobilize the patient's creative resources and help him to achieve cognitive reorganization. The goal of Adlerian psychotherapy is the reorganization of the patient's life style, which is a concomitant of a diminished sense of insecurity and a strengthened social feeling.) This leads, in turn, to a less rigid and more accurate appraisal of reality, to better relationships with others, and, finally, to the fulfillment of the patient's creative potentialities.

Therapeutic process. Therapeutic change is accomplished in several steps, which partly overlap and always dovetail.

Initial phase of therapy. A relationship is established between therapist and patient which enables the patient to experience "contact with a fellow man." The patient's mother may have failed to fulfill her duty to interpret society to the patient in childhood. In that event, the therapist must assume this responsibility as the first step in the therapeutic process, although he will be heavily handicapped in his attempt to convince the adult patient to correct a scheme of apperceptions which he developed in childhood.

Second phase. The therapist, and then the patient, learn to understand the patient's life style and goal. The therapist's understanding of the patient is, in

fact, essential if a reconstructive relationship is to develop and persist throughout therapy. On the other hand, the patient's increased insight into his motivations, intentions, and goals contributes to, but is not a prerequisite for, therapeutic change; his insight may follow and not necessarily precede changes in behavior.

Third phase. The patient's inferiority feelings and fears diminish; he develops a positive self-image; and, concurrently, his social feeling is strengthened.

Fourth phase. The patient is encouraged to select and try out new ways of relating to people and to enjoy new methods for coping with the tasks of life.

The third and fourth steps in the therapeutic process may occur with or without insight. Adler believed that insight was not a necessary precondition for cure in all cases. He suggested that in some cases the neurotic's self-centeredness might give way to a healthy interest in others, either because of a favorable change in the patient's external situation or as a result of the therapist's encouragement and the diminished anxiety achieved in therapy. Again, inevitably, new social experiences will bring about slow changes in perceptual organization and concept formation even when the patient does not comprehend the dynamics of his behavior. Although this kind of perceptual reorganization is undoubtedly due to the therapeutic experience, it is similar to the noninsightful learning which takes place before the patient enters therapy.

Psychotherapeutic techniques. "Encouragement" was Adler's main weapon in combating the schizophrenic's life style. The patient's exaggerated sensitivity can be overcome by the therapist's kindly and consistent interest in him, despite his bizarre and contradictory behavior. As a result of this experience in human relatedness, the patient becomes more hopeful that he will achieve some of his goals; and he learns to feel less isolated and begins to feel that he is part of society.)

In the one-to-one relationship, or in the therapeutic milieu of a group or an institution, the therapist must combine acceptance of the patient as he is with the therapist's awareness of the kind of person the patient can become once the neurotic pattern and goals have been removed and the patient's potentialities have been freed to develop. The therapist's assumptions of the possible healthy self in the patient's future will, of course, influence his attitudes toward the individual patient. (In a broader sense, however, such an awareness will also influence the establishment of desirable social norms in a given therapeutic group or milieu.) If both therapist and patient understand and accept what Adler termed the "logic of man's communal life," and what Erikson has called the "societal meaning in frustrations," then even a delinquent or psychopath can be reeducated in a proper therapeutic environment. This would imply an en-

environment in which he feels accepted as a full member of society, fully responsible for his actions and able to learn new ways to correct his failures.

In individual psychotherapy, the patient's behavior is interpreted as a unitary field of interweaving psychological forces, all of which are directed toward achievement of his life goal. The therapist must be attentive to details and sensitive to the clues offered by the patient's verbal and nonverbal communications. These must be combined into a meaningful whole, which forms the image of the patient's life style. This combining of parts or fragments to form a whole is, needless to say, a difficult and challenging task for the therapist. It may be helpful, therefore, to delineate four types of observation which are generally regarded as particularly important in the creative reweaving of the fabric which constitutes the patient's life style.

Early recollections. Reports of conscious memories of childhood demonstrate that the child makes active choices from the multitude of experiences to which he is exposed daily and that some incidents are regarded as particularly important and memorable. The nature of these memories—whether pleasant or unpleasant, whether the child's participation in the experience was active or passive, the role played by each person in his environment—will determine the child's (and subsequently the adult's) apperceptions and expectations. In other words, these early recollections can be used as a projective test, in order to infer a great deal about the patient.

Family constellation. An understanding of the patterns of interaction and dynamic group forces and the structure of the patient's original family enables reconstruction of the matrix from which the adult has formed his picture of "reality." Thus, his impressions of his environment will depend, in part, on whether he is an only child, or the first, middle, or youngest child, an only boy among girl siblings, or vice versa. The term "masculine protest" refers to the attitude of a boy or girl who is raised in a patriarchal culture, in which the "real man" is respected and admired and the feminine role connotes submissiveness and immaturity. In contrasting the biological concept of "penis envy" with the social construct of "masculine protest," Adler again anticipated some of Erikson's work on this topic.

Dreams. In wakefulness and in sleep, all psychic activities serve to strengthen the individual's sense of self-worth and protect against damage to his self-esteem. Thus, "conscious," "semiconscious," and "unconscious" processes contribute to the unity of life style and serve a single life goal. The understanding (and interpretation) of dreams is meaningful only in this context. Sexuality and sexual strivings are part and parcel of the individual's life style. To reduce all dream content to its sexual implications precludes an understanding of the dream-

er's orientation to his own future. In his dreams, the patient reveals his imagined or fantasied solutions to his pressing problems and his expectations for the immediate future. His dreams also reflect the patient's self-concept and his concepts of the nature and meaning of life.)

Behavior in the therapeutic situation. The patient frequently misunderstands and makes an unconscious effort to restructure the therapeutic relationship. This may be attributed to the fact that the patient experiences the therapist's attitude and personality in accordance with his (the patient's) life style, and his response to the cues from the therapist will be determined by his life goal. To illustrate, a dependent patient may try to "prove" his helplessness in order to manipulate or exploit the therapist. The distrusting, guarded patient continues to protect himself against the humiliation and hostility he encountered as a child. The patient who needs to feel superior to compensate for real or imagined handicaps continues to compete with and test the therapist.

Adler considered the Freudian concept of transference as misleading. He maintained that the patient's sexual involvement with the therapist was an unnecessary obstacle to therapeutic progress. On the other hand, despite his safeguarding operations, the patient expects his therapist to be trustworthy, reliable, warm, able, and interested in his welfare in the here-and-now situation. Adler was convinced that every human being, with his aptitude for social interest, needs and wants this kind of relationship.

The therapist understands the patient's resistance to change as a fear of giving up the attitudes he developed in childhood as part and parcel of his life style. An active approach, based on the therapist's empathy and expressed awareness of how much courage the neurotic patient requires to seek creatively an alternate choice for his life goal, will restore the patient's faith in himself, help him to realize his strength and ability, and foster his belief in his own dignity and worth. Without encouragement, neither insight nor change is possible.

During this process of reeducation, therapeutic neutrality should be replaced by the therapist's firm insistence on his right to his own values and his respect for the patient's right to be different. The therapist may have religious values or ethical subgroup values which differ from those of the patient. His frame of reference concerning sexual morality and the structure of roles within the family setting may differ from that of the patient. He must be able, nonetheless, by thinking about these issues objectively and rationally, to recognize the patient's integrity and accept his values, if these are genuinely held and are directed toward social feeling.

If the patient's uncertainty regarding ethical values arouses guilt feelings, it is particularly important for the therapist to discuss the question of right and

wrong from his own viewpoint, as well as from that of the patient. Once the problem of values has been resolved through such therapeutic cooperation, the next step in the progression is to encourage the patient to use his guilt feelings as a motivation for change. Neurotic guilt is destructive; active remorse is purposeful and constructive.

The therapist's rapport and empathy with the patient, his optimistic attitude with regard to the possibility of change, and his responsive and responsible actions increase the patient's belief in his own worth. Emphasis upon the past may perpetuate and strengthen neurotic attitudes. An explanation of persistent neurotic symptomatology which focuses on the purpose it serves is a useful therapeutic aid in unlocking the static feedback mechanism of early experiences, which has created a vicious circle of distorted apperceptions, leading to behavior which is motivated by irrational anxiety and discouraging any attempt to correct faulty expectations and concepts.

Current Status of Adler's Individual Psychology

As this section has attempted to indicate, Adler's basic thinking differed profoundly from Freud's. Whereas Freud created a theory in which man's psyche was divided into discrete, sharply defined entities, Adler explained human nature in terms of continuous, interweaving processes. His field approach led to the concepts of life style, implying the continuity and unity of the living organism, and of social feeling, emphasizing the embeddedness of the human organism in society. These viewpoints anticipated many later developments in psychology and psychiatry.

Harry Stack Sullivan's "self-system" has much in common with the Adlerian concept of life style. Sullivan's ideas concerning the importance of the patient's social environment and the effect on the individual of his social relationships, and vice versa, are congruent with Adler's concepts. Karen Horney acknowledged the similarities between her own system and Adler's. And, again, Adler's concept of motivation as movement toward an unconscious, subjective goal corresponds to the notion in Gestalt psychology that the future is "part of the actually present phenomenal field." As Cantril stated more recently, "Our perception depends in large part on the assumptions we bring to any particular occasion; it is 'transaction with the environment.'" Or, phrased differently, "We seem to give meaning and order to sensory impingements in terms of our needs and purposes, and this process of selection is actively creative." In these two sentences, we find the Adlerian concepts of the style of life, the scheme of apperceptions, and goal-directedness expressed. Similarities in the concepts elaborated by Adler, on the one hand, and by Kurt Lewin, Gordon Allport, Kurt Goldstein, Martin Buber, and the theories of phenomenol-

ogy and existential and humanist psychology, on the other hand, have been pointed out frequently.

The comparisons and parallels cited above are an indication that Adler's conceptual framework consists of strong, bold outlines which allow other scientists to fill in their own detailed viewpoints and preferences. Adler staked out the ground, as it were, for the development of present day integrative approaches. Because he was intuitive, his system in no way contradicts modern thinking and has not required revision. Adler's conceptual scheme provided a useful instrument in his daily practice. As a physician and psychiatrist interested in the cure and prevention of mental disorders, his efforts were directed to the kind of social action which would be described as "community psychiatry" today. He established child guidance clinics, trained teachers in the dynamics of classroom mental hygiene, discovered methods to reeducate juvenile delinquents, and demonstrated methods of family diagnosis and treatment to workers in the helping professions.

Adler contributed to the field of psychotherapy by stressing the methods and success of short term therapy. The techniques which he advocated for this purpose were confrontation of the patient with the self-defeating and self-deceptive attitudes which made him cling to his symptoms; the purposeful use of interviews and explanations; the therapist's active engagement with the patient; and his hopeful outlook toward the possibility of cure, based on the conviction that every human being, even the psychotic and psychopathic, would prefer to be socially useful and accepted. And, because the techniques and attitudes developed and elucidated by Adler have markedly increased the impact of the therapeutic situation and have, thereby, made it possible to shorten the period of treatment, therapy has become available to many who could not afford it otherwise.

7.2 KAREN HORNEY

JACK L. RUBINS M.D.

What is known as the Horney theory systematizes the concepts formulated by Karen Horney during the last 15 years of her life, between 1937 and 1952. These were set down, in part, in five books and in numerous journal articles and, in part, were presented in formal and informal discussions and lectures. In this 15-year period, Horney's ideas were modified. This discussion will refer to the final version of the theory as it is elaborated in her last published volume, *Neurosis and Human Growth*. Other modifications which have occurred as ideas and which were only implied in Horney's original work have subsequently been clarified, defined, and elaborated by her colleagues and successors. Remaining gaps continue to be filled, and the Horney theory expanded through its application to areas of psychiatry which were not dealt with previously.

The need for this new theory was based on three categories of clinical observation. (1) The difference in the symptomatology of neurosis which was characteristic of the 19th century as compared with the symptomatology which predominated during the 20th century, and differences in the symptomatology which was typical of Europe, as compared to that typical of the United States. These differences indicated the need to ascribe greater importance to the influence of sociocultural factors on individual development. (2) The fact that the variation in symptoms from one patient to another could not be adequately explained on a purely biological basis. This raised questions about the validity of certain generally accepted postulates, such as the existence of immutable instinctual drives and developmental phases, or sexual conflict as the root of neurosis. In brief, these questions underscored the need for a more individualistic yet more holistic view of psychic organization. (3) The dissatisfaction with current therapeutic results. Many patients, after a "successful" classical

psychoanalysis, continued to suffer from residual symptoms, such as discontent, depression, or disturbing personality traits, despite the seemingly good insight they had achieved into their unconscious mechanisms. This apparent paradox demanded a reevaluation of the nature of neurosis and the process and goals of therapy.

Accordingly, the Horney theory differs from the classical (Freudian) theory in several respects. These differences are cited throughout this section and described in further detail in the specific context in which they arise. For the convenience of the reader, they may be summarized briefly as follows. Horney did not accept the libido theory and the postulates derived therefrom (stages of psychosexual development, the Oedipus complex, the economic concept of a fixed quantity of libidinal energy, libido-cathexis, infantile fixation, and regression). While recognizing the importance of sexual drives, she did not hold these to be universally uniform or immutable in development; nor did she consider them the cause of neurosis. In their place, cultural factors and disturbances in interpersonal and intrapsychic development were seen to be the cause of disturbances in sexual functioning and of neurosis in general. Horney also rejected the topographical hypothesis of the psyche (id-ego-superego), and, in its place, postulated a more holistic, dynamic concept of the self. A different emphasis was placed on the significance of childhood events; these were not seen to be a direct, relatable cause of adult neurotic symptoms, nor were infantile attitudes necessarily the prototypes of adult behavior, through the repetition compulsion. Rather, infantile attitudes were seen as initiating neurotic development, which then becomes self-perpetuated. Concomitantly, Horney rejected the concept of transference in its narrow sense, since childhood attitudes, as such, are not carried over into analysis. In its place, the doctor-patient relationship was conceptualized as a complex of current interpersonal attitudes, expectations, etc. The goals and techniques of this psychoanalytic psychotherapy are also different from those of Freudian therapy; but these differences will be discussed later on.

Horney theory accepts the Freudian concepts of psychic determinism and unconscious motivation (although Horney's concept of the unconscious was broader than "the unconscious" of classical psychoanalytic theory, and the motivating factors are different); of emotional conflict as the cause of neurotic anxiety and defensive maneuvers (although the conflictual polarities are broader, and may be conscious or unconscious); of repression; of resistance; and of the value of dreams in therapy (although these, too, are seen in a broader, dynamic sense).

Horney was primarily an experimental clinician, concerned mainly with therapy. Her theories evolved from observations of her patients, and were confirmed by further observations. The Horney theory reflects

this clinical orientation. Thus it includes a philosophy of human nature and morality; theories of human motivation; concepts of normal and pathological personality organization and functioning; and the elaboration of a therapeutic technique.

Theory of Personality Organization and Functioning

The term "personality structure" (which is used interchangeably with character structure) appears often in Horney's writings but is not defined in psychological terms. Its meaning can be inferred from the clinical context in which it appears, however. Thus, the concept has no static model; rather it is used holistically, functionally, and dynamically.

Holistic view of personality. Holistically, the individual is seen as a unit within a social framework, ever influencing and being influenced by his environment. Particular aspects of personality functioning which are symptomatically significant may appear in the foreground or may be focused upon for clinical purposes (e.g., physical or emotional factors, intrapsychic conflicts, environmental maladjustments, specific attitudes or behaviors, sexual or work functions), but this isolation is artificial. Such factors can be truly assessed only in terms of the total individual gestalt.

Functional aspects. Functionally, personality may be said to consist of the total attributes which characterize the constantly changing organization of the individual. These include his biological and social needs, behavioral traits, feelings, attitudes toward others and self, self-evaluations and concepts, social values, expectations, inhibitions, and conflicts. The normal personality is defined in terms of generic tendencies, as contrasted with the neurotic. Greater value is placed on some attributes than on others. They vary at different times; some are more easily expressed and experienced; some exert a greater influence on behavior; some are more conscious; some are more subjective, others more objective.

Dynamic viewpoint. The dynamic viewpoint postulates that each attribute has a peremptory force: it is simultaneously created by the individual and acts upon him, demanding satisfaction, producing strivings, or pressing toward action. One attribute may reinforce or conflict with another.

Personality, then, constantly changes in observable ways, in definite directions, with definable rhythms. (This concept has been emphasized by Kelman in his continuing studies of the psychoanalytic process.) It is partly because of this holistic, functional, dynamic view of personality developed by Horney that Freud's structural theory of personality and his economic theory of a fixed quantity of psychic energy were held untenable. The Freudian concept of the ego, for instance, is considered essentially a reification of dynamic principles, forces, and subjective experiences. On the other hand, Freud's concepts of unconscious

motivation, activity, and determinism were accepted by Horney. However, her view of the motivating factors, acting consciously or unconsciously, was quite different from that of classical psychoanalytic theory. According to the Horney theory, motivating factors derive from current personality attributes described above, rather than from infantile libidinal strivings which are carried over from childhood through the repetition compulsion.

Triple concept of self. Originally, Horney sometimes used the terms "personality" and "self" synonymously. Basically, however, personality refers to just one aspect of the self, and in the later version of her theory, the term "self" almost completely replaced the use of the term "personality." Understanding the triple concept of self is crucial to the understanding of Horney theory in general.

The actual self. The actual self refers to the individual as the sum total of his experience. Temperamental factors (need variations, behavior patterns, primary emotional reactions, abilities, talents, imagination, and humor) are recognized as contributors, whose determinative role is not elaborated. However, their role is less important in neurotic development than are neurogenic, environmental, and intrapsychic factors. A recent modification of the theory by Rubins stresses the importance of such factors as body image, self-concept, identity, and some temperamental qualities, in the maturational process. Vicissitudes in this maturational process modify the healthy and/or neurotic pattern in characteristic ways.

The real self. The real self is defined as a central inner force or principle common to all, yet unique in each individual. It is not conceived as a predetermined homunculus with specific attributes, but a source of constructive growth, spontaneity, energy, interest, effort, decision, clarity and depth of feeling, and resourcefulness.

Thus, the real, or central, self is equated with healthy integration and the sense of harmonious wholeness. Recent developments in Freudian ego psychology, such as the synthesizing functions of the ego, and the autonomous, conflict-free sphere of ego functioning, have taken into account some faculties of the central self, as they were outlined by Horney in this concept.

Horney maintained that, given such optimal environmental circumstances as parental warmth and acceptance, and a certain amount of healthy friction, the child who is normal physiologically and neurologically will develop a healthy personality. This view implies an optimistic, nonjudgmental philosophy of human nature and morality. Thus, according to Horney, "there exists inherently in Man, evolutionary constructive strivings—by his nature and with his own accord, toward realization of his own potentialities, and...he will evolve a set of values therefrom. The criteria of what is moral hinge on what

encourages optimal growth as a human being, as contrasted with what is destructive or obstructive." This statement opposes the notion of the death instinct, in that the individual's destructive tendencies are considered to be neurotic, rather than innate.

The idealized self. The idealized self, which is the third concept, is solely a neurotic manifestation and will therefore be discussed below, in connection with Horney's concept of psychopathology.

(Theory of Psychopathology)

Redefinition of neurosis. Horney's holistic orientation requires a redefinition of neurosis, with attention shifted from specific symptoms to total personality disturbance. Accordingly, Horney conceived of neurosis as a disturbance in the total personality which (1) has its source in distorted parent-child relationships, and is subsequently self-perpetuated; (2) is characterized by distortions in the individual's relationships with others and self, which stem from emotional conflicts and anxiety, and unconscious dynamic intrapsychic efforts to avoid the disintegrative effect of these conflicts; and (3) results in discrepancy between potentials and achievement, in rigidity and suffering, and in impairment of function in most areas of living.

The rigidity of neurotic reactions, and their capacity to induce conflict and anxiety are due to the compulsive quality of the attitudes from which they derive. These attitudes have a driven quality and "must be abided by regardless of the individual's real wishes, feelings or interests, lest he incur anxiety, feel torn by conflict, be overwhelmed by guilt feelings, feel rejected by others." Such attitudes toward self or others are designated as neurotic trends and may include needs, traits, drives, and expectations. Other criteria of compulsiveness would include indiscriminateness, insatiability, and exaggerated reactions to frustration.

It is evident that the formation of the neurotic personality involves both intrapsychic and interpersonal (cultural) factors. Horney was one of the first psychoanalysts to stress the importance of cultural influences (although, in her final volume, she accorded greater weight to intrapsychic processes).

Cultural determinants of neurosis. Cultural influences form the framework of neurosis in several ways. As culture bearers, parents determine the child's generic values, self-concepts, and some behavior patterns. However, whether the child conforms to these influences or rebels, imitates, adapts, etc., will ultimately depend on intrapsychic processes. If they conflict with the child's natural tendencies, cultural influences may blur or otherwise undermine his identity. In a broader sense, cultural influences will determine what is considered healthy or neurotic for a particular society. They will also influence the formation of the idealized self, although the specific characteristics will be neurotically determined. Finally,

specific neurotic conflicts may be reinforced by or reflect similar conflicts between cultural values; for example, competition and success versus brotherly love and humility; alleged freedom of action versus the limitations imposed by society; the stimulation of desires as opposed to the real difficulties which may interfere with the satisfaction of such desires.

Psychodynamics of the neurotic process. Early childhood experience, in the over-all sense, is considered to play a crucial role in the genesis of neurosis. This is not to be confused with direct causality, however. That is, neurotic symptoms cannot be attributed to specific infantile experiences in a one-to-one relationship through the repetition compulsion, as postulated in classical psychoanalytic theory. The adult does not simply repeat childhood reactions; individual neurotic growth patterns have been superimposed on these childhood reactions. To illustrate, the final form of the small snowball which is pushed and grows larger as it rolls down a hill will depend on the slope of the hill, temperature, thickness of the snow, and the strength with which it is pushed. Thus, the form which the snowball will ultimately take cannot be related directly to the push itself. Similarly, the infant may be subjected to a wide variety of neurotically determined parental attitudes, including excessive expectations, overstrictness, "smother love," or rejection, to mention a few. To counteract these distortions in parental attitudes, the infant will develop those reactions and traits which can best insure feelings of security and safety. Despite a universal biological dependency, infants can react to parents in many ways. These possible reactions have been grossly classified as (1) "moving toward," by accepting love, closeness, and realistic dependency; (2) "moving away," into solitude, privacy, and self-containment; and (3) "moving against," through friction, self-assertion, and protest.

Genesis of anxiety and conflict. The child who is exposed to rejecting parental attitudes will react with vague feelings of loneliness, helplessness, and fear of the potentially hostile world that surrounds him. This reaction is called basic anxiety. To avoid this anxiety, he develops attitudes toward his parents which are either compulsively submissive, aggressive, or detached. These attitudes have been called neurotic trends, or drives. When one predominates, the others are repressed but continue to exert a dynamic force. Their expression may alternate or be modified by traumatic external events, personal experience, cultural demands, the development of other neurotic mechanisms, or changes in the instinctual drives, particularly the sexual. Anxiety, then, is the mainspring from which these attitudes (i.e., neurotic trends) gain their intensity and pervasiveness. The existence of such attitudes, which are simultaneously contradictory and compulsive, becomes intolerable and incompatible, creates basic intrapsychic conflict which generates further anxiety. Generally, by early adoles-

cence, this constellation of attitudes is grossly defined in the personality structure, although it may continue to change.

The preceding description challenges the classical psychoanalytic theory of psychosexual development, including the concepts of fixed biological phases of development which are related to specific body regions, the sexual nature of child-parent relationships (Oedipus complex), and regression. In contrast, Horney attributed excessive preoccupation with a genital (or other) organ function to a parental attitude, e.g., maternal overconcern or rigidity regarding this function. She ascribed the adolescent's feelings of sexual attraction for the parent of the opposite sex or homosexual tendencies to parental seductiveness or unconscious rejection of the child's given sexual role, rather than to inherent libidinal tendencies. Sexuality, *per se*, and the conflicts surrounding it, were not considered causes of neurosis. On the contrary, neurosis may cause disturbances in sexual feelings, attitudes, and behavior. This viewpoint has been elaborated in numerous articles by Weiss on compulsive sexuality, and by Gershaman on homosexuality.

There is an admitted gap in the application of these principles of childhood development to the individual child and adolescent. Horney was not a child analyst. Her formulations were developed through reconstruction of the childhood history of adult patients. Only recently has her theory been adapted and applied to this younger age group. Thus, some of her colleagues engaged in this area of practice have described variations in parent-child interactions, and consequent modifications in the attitudes of the child. Maturative phases have been schematized and related to the neurotic process by others. Recently, Rubins described characteristic changes in the clinical picture of the neurotic personality in adolescence. These changes are precipitated by aggravation of the neurotic conflict by increased social demands; by intensification of neurotic self-idealization (often with extreme fluctuations), as confusions over identity emerge; by the threat to a previously successful neurotic solution posed by newer reality situations; and by an increasingly acute awareness of the alienation from self.

Characterological defenses against neurotic trends. To allay anxiety and resolve the conflict between neurotic trends, the child—and, later, the adult—must institute further protective measures, an evolution which is the basis for the self-perpetuated neurotic development. These measures consist of characterological defenses or solutions to conflict (in contrast with the symptomatic defense mechanisms usually described by the Freudian school, such as repression and denial, which are more limited and focused). There are three general types of solutions or approaches to inner harmony: major, comprehensive, and auxiliary.

Major solutions. The three major solutions, self-

effacement, expansiveness, and resignation, extend and expand the original compulsive trend into a way of life. The patient may have some awareness of his use of these solutions, but their ramifications, intensity, resistance to change, and their implications in terms of his general adjustment are largely unconscious. According to each orientation, the neurotic assumes certain characteristic personality traits, needs, attitudes toward others and self, values, fears, sensitivities, and inhibitions.

Self-effacement. In the self-effacing solution, love has the greatest appeal for solving life's difficulties. The individual is, in fact, compelled to be loving and lovable, self-sacrificing, compliant, sympathetic, dependent; he sees these qualities as having high value. He needs to be loved, to give in rather than argue, to please, to be approved of. He is oversensitive to and fears criticisms, rejection, abandonment, to the degree that he may anticipate these reactions without justification. Concomitantly, he inhibits any expression of aggression, initiative, competitiveness, striving toward success; he considers these negative traits. As might be expected, he can readily admit to weakness or unimportance; he overidentifies with underdogs. Unconsciously, he identifies with his despised self; in contrast, other people are always superior, nicer, more competent or intelligent. His attitudes often cause him to be taken advantage of, and he unconsciously invites such treatment.

In its extreme form, this solution may be manifested as morbid dependency and is often characterized by neglect of self so severe as to result in self-elimination. Helplessness has great appeal; consequently, unconscious acting out through illness, suicide, or sexual perversion may occur. (It should be noted that sexual masochism refers to only one aspect of this generally masochistic attitude which involves the total personality.)

Expansiveness. The expansive solution requires mastery over life and over others in the neurotic sense of domination and self-glorification. Certain personality traits have positive values for such an individual. These include hardness, strength, efficiency, domination, aggression, shrewdness, ambition and success, and insensitivity to the feelings of others. In brief, he needs to control, have his way, compete and outdo, and gain prestige. He shuns affection, sympathy, and trust as weaknesses; he is afraid to admit to error or imperfection, even illness, for these represent negative values. He sees himself without limits, confident and superior. He mistrusts others and sees them as potential competitors.

The three subforms of the expansive orientation are based on the particular aspects of the idealized self-image with which the individual identifies.

The narcissistic-oriented person identifies with his glorified attributes. This differs from the concept of narcissism postulated by classical psychoanalysis: the person is not in love with himself (libido cathected

onto his own ego), but with an irrationally glorified concept of his self.

The perfectionist-oriented neurotic identifies with the irrationally high standards he has set and is driven to live up to them. Unconsciously, he may experience himself as perfect and look down on others with contempt; but, at the same time, he is constantly threatened by a fear of failure or by awareness, however subtle, that his high opinion of himself is exaggerated.

The arrogant-vindictive neurotic identifies with his proud self. Irrational pride is common to all neuroses, but it is most intense and evident in these individuals who are obsessed by their need for power and domination. It renders the individual most vulnerable to hurt pride reactions, leading to vindictiveness (acute or chronic), and the need for retaliation and triumph. Sadism, in this context, refers to the vindictive satisfaction which is associated with fulfillment of the neurotic need to subject others to pain or indignity. While this need may be related to sexual activity, this is only one area of its expression.

Resignation. The solution of resignation differs somewhat from the other two in its dynamic motivation. Self-effacement and expansiveness emerge after direct repression of contradictory orientation. The resigned person, on the other hand, not only strives for freedom from conflict, but for freedom from all emotional feelings; therefore, both of the preceding orientations must be repressed. They continue to exert a conflictual effect from within, however, which may emerge when the resignation is dealt with in therapy. The traits of resignation are mostly negative; aloofness, reduction of material wants, detachment. The individual's needs are for privacy, not to compete, not to be involved or committed; he wants to be self-sufficient and independent. And, concomi-

tantly, he fears influence, obligation, intrusion, coercion, pressure, change, which he may feel to emanate from others, even if this feeling is without foundation. His need for detachment renders emotional ties intolerable; anticipated closeness, through sex and marriage, may cause anxiety. All awareness of such attitudes as love or aggression is inhibited. The attitude toward self is one of objective interest and numbness, and others are experienced as strangers. The resigned orientation may take one of three forms.

Persistent resignation includes the traits described above, plus inertia, disinterest, aversion to activity (although routine or sporadic work may be well done), and feelings of futility.

In the rebellious form, passive resistance becomes active and is directed against environmental factors or inner restrictions.

In the third form, shallow living, the degree of futility, hopelessness, and emptiness is extreme. To avoid it, the person is driven to constant activity and distraction in sex, sociability, participation in others' ideas. Detachment then deteriorates into unrelatedness; emphasis is on fun without real enjoyment or on prestige or opportunistic success without any sense of accomplishment; or the person may become a well adapted automaton.

These orientations do not describe a character "typology." They indicate forms of development, related groupings of attitudes and peremptory traits which may not be concretized as behavior. They are seldom present in pure form; there may be admixtures or shifting, as more conscious solutions are found to be inadequate and others are substituted. Thus, we see the pseudocompliant individual who is dependent in order to manipulate others, or the basically resigned person who presents a facade of submissiveness or dominance or alternates between these facades.

FIGURE 1. Schematic representation of neurotic development according to Horney theory (modified).

Actualization of the idealized self. Even after the major solutions described above have been applied, conflict still exists. The attempt to attain a greater degree of unity, however spurious, requires the more comprehensive solution of self-idealization. This process involves the actualization of the idealized self. Fundamentally, it is a means of avoiding psychic conflict by rising above it. Initially, the glorified image is conscious, limited to certain activities and aspects of self; it is often experienced in fantasy or daydreams, especially in children and adolescents, with awareness, at first, of its irrational, imaginary, exaggerated nature. However, it progressively encompasses more of the personality, becomes more organized, and partly or totally unconscious. "Eventually the individual comes to identify himself with this integrated idealized image... it becomes an idealized self" which he is driven compulsively to live up to and maintain. This is so because it satisfies needs, permits avoidance of anxiety and other painful feelings, promises fulfillment of imagined capacities, transforms weakness into virtue, and provides a feeling of identity and unity. Its precise nature in an individual is determined by "his own special experiences, his earlier fantasies, his particular needs, his given faculties... and his special solution for his basic conflict." It is irrational and unattainable, aiming toward the ultimate and absolute. It involves specific trends, attitudes, and values: "compliance becomes goodness; love [becomes] saintliness; aggressiveness becomes strength, leadership, heroism, omnipotence; aloofness becomes wisdom, self-sufficiency, independence." It may also involve elements of the body image. Indeed, selective inclusion of parts of the body image in this self-glorifying and self-denigrating process may be an explanatory factor in specific psychosomatic symptoms. (See Figure 1.)

Auxiliary solutions. The total neurotic superstructure remains fragile, giving rise to disruptive feelings of strain and tension. Additional auxiliary measures to preserve inner harmony, sometimes designated as pseudosolutions, become necessary. Only five of the many auxiliary solutions postulated in Horney's earlier work were retained in the final version.

Externalization consists of experiencing inner processes or feelings as occurring outside the self. It is broader than the traditional (i.e., Freudian) concept of projection, in which the individual ascribes his own rejected personal tendencies to others. It may be total, i.e., seeing all one's qualities in others; or active, converting one's self-contempt to a contempt for others, or anger at one's own faults to anger at these same faults in others; or passive, with inner coercion felt as coercion by external authority. The tendency may be so complete as to constitute a vicarious way of life, i.e., experiencing one's self only in and through others. It is particularly evident in those individuals who show a paucity of inner emotional experiences. In such cases, idealized attributes, as well

as the actual qualities of self, may be externalized so that a spurious sense of identity and worth is derived through identification with another person who is seen as ideal. This has been advanced as one of the mechanisms involved in homosexuality.

Compartmentalization (also called psychic fragmentation) is the experiencing of self as consisting of unconnected parts, and of one's attitudes as without interrelationship (either cause-effect or contradictory).

Alienation from self is both a defensive measure and a consequence of the neurotic process. It is active, achieving (among other results) the relief of tension by blurring those real self attributes—genuine wants, feelings, and beliefs—which conflict with neurotically idealized qualities.

The measure of automatic control, which is largely unconscious, checks the generation of impulses and feelings and their expression. Instead, these impulses and feelings may be expressed somatically. Physical manifestations may include muscle tightness, constipation, facial tension or tension headaches, breathing spasms, etc. It may apply to all feelings, but selectively permit the expression of some, such as crying, in neurotically exaggerated forms.

Supremacy of the mind (intellectualization) refers to the use of intellect to avoid experiencing emotional conflict. More specifically, it enables the person to observe objectively what occurs within. Thus, he may accumulate information about himself without applying it to his life. Above all, he values the mystic power of knowledge: "to know is to be able to control." This mechanism, which involves logic and reasoning, may prevent free association in therapy. It may also trigger panic when the individual is abruptly threatened with loss of control by approaching sleep or anaesthesia, or intoxication, or when he is forced to "let go" in sexual activity.

Neurotic claims. Movement toward actualization of the idealized self is expressed differently to the outside world than to the self. The neurotic expects to be treated by the outside world in accordance with his glorified self-concept. Irrational needs, based on fears, inhibitions, and feelings of deprivation, are thus transformed into claims. Unaware of his self-exaggeration, he is not conscious of the excessiveness of his expectations, or that the feeling that he is entitled to certain privileges is inappropriate. Such claims are general to all neurotics, or specific for each solution. Neurotic individuals may feel they are entitled to special consideration or deference; that they should be exempt from the consequences of their actions; that they are not vulnerable to illness or mishap; that they are immune to aging or death. They may believe they deserve utter obedience from others; "understanding" or love, regardless of their own attitudes. This egocentricity reveals itself in the expectation of fulfillment without proportionate effort or consideration of

the feasibility of one's goals. The clinical effects of long standing claims may be chronic; the neurotic patient feels he has been treated unfairly and must "get back at" the world; or these claims may produce chronic inertia, envy or depression, or, eventually, a feeling of doubt as to what rights he really does have.

Neurotic demands on self. The neurotic molds and drives himself to live up to his irrational self-concept through a system of shoulds, musts, demands, and expectations, whose specific nature varies with the neurotic structure. These inner dictates grossly determine what the person should or should not be, know, feel, do. They are largely, though not always, unconscious. In any event, the "tyranny of the shoulds" exerts intense pressure on the individual, although there may be some variation in degree of intensity.

The neurotic's reactive feelings about what is, in effect, an inner authority, may vary. He may actively accept authority, welcoming a regulatory system which holds in check repressed feelings the emergence of which might be feared as disintegrative. On the other hand, he may feel ambivalent, or passively resist, or actively rebel against such an inner authority. This, in turn, renders him hypersensitive to coercion from external authority. Indeed, his transformation of a rational, guiding external authority into an irrationally coercive one may be due in part to the externalization of intense inner dictates. Finally, his attitudes toward authority may be in conflict. The awareness of his need for such authority may conflict with his resentment against it. He may be compulsively submissive in one situation and assume an authoritative, dominating role in another.

This construct has been compared with the classical psychoanalytic concept of the superego, but there are differences between them. In Freudian theory, the superego represents internalized parental-cultural values; it would correspond to conscience. The "shoulds," however, do not constitute a genuine moral code, nor do they represent an attainable ideal. Aimed at some form of irrational perfection, they are always neurotic. The distinction between genuine morality and neurotic pseudo morality and guilt due to failure to reach the absolute has been clarified by Weiss in his papers on psychoanalysis and moral values. Even some religious practice, generally considered to express man's optimal moral code, has been found to be motivated by compulsive, egocentric attitudes, rather than genuine religiosity.

Pride system. The idealized image achieves intense value and hold on the individual as it becomes invested with pride. Genuine pride in realistic achievement would provide a solid feeling of self-worth, but the neurotic's false pride, based on exaggerated self-concepts and spurious values, is brittle, vulnerable to challenge or threat, as when a claimed attribute is disproved by reality. Neurotic pride may take various forms, specific for each individual. These include

pride in prestige, intellect, will power, strength, honesty, lofty standards, lovability, appearance, and sexual prowess. The typical hurt pride reaction consists of shame (failure from within) or humiliation (action from without). This may be automatically, often unconsciously, transformed into secondary feelings of embarrassment, guilt, vague irritability, or degrees of anger, ranging from sullen dislike to rage and hate. When anger must be repressed, fear, anxiety, or psychosomatic symptoms may appear as the only apparent conscious reaction. These reactions may occur not only in response to actual events, but in response to anticipated ones as well. They are followed by automatic attempts to restore pride such as a need for vindictive triumph; withdrawal and loss of interest in the situation; denial or distortion of the event; or exaggerated humor.

The neurotic feels contempt for what he is, for his actual self. Pride and self-hatred, two sides of the same coin, form the pride system. The actual attributes toward which contempt and rejection are directed comprise the despised self. They are evidence of the failure to achieve the idealized self and must be repressed. The degree of self-hatred may be extreme, although awareness may include only feelings of inferiority, ugliness, guilt, sinfulness, etc. It can manifest itself in six gross forms: (1) relentless demands on self ("shoulds"); (2) merciless self-accusation through moral condemnation, self-reproach, or self-blame; (3) self-contempt (and self-disparagement), often as a result of comparison to others; (4) self-frustration, by imposing taboos on positive activity, enjoyment, hope, striving, etc.; (5) self-torture, through masochistic behavior or dreams, or externalized as sadism; and (6) self-destructive behavior, e.g., accident-proneness, smoking, addiction, recklessness, psychosomatic illness, possibly psychoses, or actual suicide.

Central inner conflict. Self-hatred is also directed in a unique and often intense way against the real self. Since positive tendencies are particularly threatening to the neurotic idealized self-image, they must be avoided or denied. Taboos are imposed on such qualities as enthusiasm, spontaneity, productive effort, curiosity, and creativity. Although present in all neuroses, this becomes more evident during the final phases of analysis when such attributes are emerging and the restrictive neurotic superstructure is weakening. This produces a special form of intrapsychic discord, a central inner conflict. Its appearance gives the analysis a special quality. All the patient's symptoms become more intense, but they are less rigid and less threatening and incapacitating. Anxiety may increase periodically, but the patient seems better able to handle it, to stick with it, to work it through. Psychosomatic symptoms may appear or reappear, but they shift rapidly. Previous defensive trends may emerge again but they recede as the patient becomes increasingly aware of their source, significance, and

effects. There is greater awareness of assets, a growing ability to take chances, explore, be spontaneous, accept one's limitations and actual assets.

Alienation from self. Of special importance for understanding Horney's theory of psychopathology is her concept of alienation from self, particularly in view of its recent clinical applications, e.g., to the sexual perversions, to the problem of identity which has become an area of interest in every discipline, and to the phenomena of depersonalization and psychoses. Alienation is an active defense, as well as the outcome of the over-all neurotic process. The various neurotic mechanisms—compulsive distorted self-concepts, shoulds, claims, self-hatred—all combine to lead to this result. It is a process in which the individual moves away from his experiential center and genuine identity, to create a pseudo identity and pseudo self.

Some manifestations are objectively observable; others are subtle and subjective. Some patients lose awareness of physical activities or body attributes. They may exhibit dullness of eyes or face, few spontaneous body movements, or poor coordination. They may be unaware of visceral sensations. There may be numbness of limbs or an attitude of impersonality toward the body, "la belle indifférence." There may be a lack of capacity to feel, of awareness of feeling, or of depth of feeling. The patient may be angry, happy, or sad, without being aware of it, so that he will even express astonished denial if it is pointed out. Some patients are shocked to see themselves in a mirror, or to hear their voices recorded. They may have no emotional response to beauty, art, or other stimuli. They may complain of emptiness, deadness, haziness of feelings, thoughts, or relations with others. They may speak of "one" or "you" instead of "I," and describe inner experiences in terms of external events. This vagueness may extend into curious dissociated states bordering on the split personality or trance. Particularly severe forms are the amnesias or depersonalization states.

The vagueness may be experienced as a feeling of discontinuity with the past; these patients may have few or hazy memories, or feel little connected with their childhood. There may be a blurring of body image or identity in all its aspects—size, gender, color, body configuration. There may be lessened energy, ranging from unsustained effort to complete inertia, although, at times, there may be neurotically driven hyperactivity in some areas. Directive powers weaken, and indecision and uncertainty become increasingly apparent. Or the patient may be unwilling to assume responsibility for his actions. Primary distortions of the maturational growth process (i.e., formation of body image, self-concept and identity) may produce characteristic modifications of this alienation from self. The degree and nature of such alienation may be of special significance in explaining the etiology of certain forms of schizophrenia.

Symptom formation. With emphasis on the whole

patient (character structure)—course of development, process, patterns, intrapsychic movements—the isolated pathological symptom recedes in importance. Neurotic symptoms are characterological; they are classified as distorted attitudes, or areas of living in which such distortions become manifest. So-called "typical" symptoms—anxiety, fear, somatic manifestations, sexual dysfunction—are not considered in terms of their biological origins. Specific symptoms are produced by disturbances of personality; they can be studied only in these terms and understood only in the context of the total personality. The character structure and its vicissitudes must be kept in focus at all times. The symptoms are indicative not only of pathology but also of the adaptive measures employed to provide a degree of integration and unity, however shaky.

Anxiety. It is debatable whether the first basic anxiety could be considered true anxiety. Its precise nature requires further research. However, once the neurotic trends are established, true anxiety is generated. The development of the neurotic superstructure extends the possible area of emotional conflict between opposing trends, the idealized and despised selves, contradictory shoulds, and real self and neurotic attributes. Conflict and anxiety are intimately related, but the anxiety-producing conflict can no longer be seen simply as ego versus id. The Horney-oriented analyst, when confronted with anxiety in a patient, must ask: "What is endangered, and what is endangering it?" In effect, any pride-invested aspect of self that has subjective compulsive value may be endangered, either by a contradictory internal tendency, or by disapproval from without.

The absence or presence of anxiety is not an absolute criterion of pathology for several reasons. First, emergent anxiety may be repressed due to excessive control, pride in serenity, or some other neurotic attitude. It may not even arise, owing to feelings of alienation. Or other emotions, such as rage, humiliation, or embarrassment, may replace it in apparent direct response to threat. Second, not all anxiety is neurotic. Healthy, constructive, normal anxiety may be evoked in response to positive movements, or when genuine values are threatened, and it is essential for mobilizing constructive activity. In lieu of the term "normal anxiety," Kelman has introduced the concept of tension with a mean variation for each person; neurotic anxiety occurs when the mean limit is exceeded. Instead of normal or neurotic anxiety, the concept of rational versus irrational sources of anxiety has been postulated.

Fear. Whereas anxiety is the imminent coming to awareness of a threatening, conflict-producing factor, fear is the reactive feeling to the very possibility of such emergence. Fear may be generalized; it may focus on exposure of pretense or duplicity, on failure, on injury to pride, on change in the status quo, on loss of control, etc. Other fear may be more directly

related to special neurotic attitudes: fear of success in the self-effacing neurotic; of love in the ruthless; of closeness in the detached; of ridicule in the narcissistic. Fears may occur in special situations, such as public performances, exams, work; or a fear of closeness may arise in connection with sex. The classical phobias are but symbolized projections of general fears onto specific objects or situations.

Panic. Panic is due to the sudden collapse of a major aspect of the idealized image accompanied by the sudden threatened emergence of intense repressed conflictual drives.

Psychosomatic symptoms. Psychosomatic symptoms arise with the emergence of a repressed conflict, acutely experienced as a dilemma, or a repressed affect (anger, anxiety, joy, humiliation, sadness) which cannot be totally experienced. Such symptoms are nonspecific: the same symptom may be related to different affects, while different ones may relate to the same affect at different times. These affects, in the specific psychological inner configuration of the moment, are externalized onto the unconscious body image, parts of which act as a focus through having been distorted in the self-idealizing, self-denigrating neurotic process. Personality factors—such as pride in strength; control and invulnerability to illness; conflict between shoulds, e.g., “proper” emotional reactions and intellectualism; inability to participate in emergent anxiety—may contribute to the somatization. Psychosomatic symptoms are also seen to have an adaptive (restitutive) as well as a constructive function.

Areas of maladaptive functioning. Specific areas of maladaptive functioning have been studied, such as work, interpersonal relationships, and sexuality.

Difficulty in work may take many forms: impaired relations with one's superiors seen as authority, or with one's co-workers; inability to accept or delegate responsibility; inhibition in productivity, due to excessive self-demands and fear of failure; over- or underevaluation of capacities; excessive rebellion against rules or limits, resulting in poor organization of time or procrastination; over-reaction to routine problems of creating, with resultant anxiety; distractibility or inability to concentrate; or compulsive hyperactivity with scattered interests.

Sexual dysfunctions are explainable in terms of neurotic attitudes. Compulsive use of sex to satisfy neurotic needs to dominate or submit, or for closeness, is characteristic. Sexual hyperactivity (promiscuity, Don Juanism) may be motivated by inability to form deep relationships, by narcissistic standards of performance, or an insatiable need for triumph. Focal sexual psychosomatic impairments—premature ejaculation, dyspareunia, frigidity, impotence—may be due to unconscious needs to frustrate the partner, inhibitions due to rebellion against perfectionistic demands, or to a fear of letting go. Homosexuality is explained by a combination of factors: intense hatred

of one's gender attributes, derived from early parental rejection of the child's sexual role and exacerbated by neurotic self-devaluation; actualization of neurotic dependency, domination, or distance needs without related heterosexual conflicts; identification with one's idealized image (in the partner); and experience of a more unified identity in an external context.

Other areas similarly studied include schizophrenia, the adolescent psychiatric disorders, drug addiction, loneliness, the nature of creativity, group relations and therapy, mental retardation in children, and determination of individual reactions to therapeutic drugs. These are new directions in the application of the Horney theory.

Principles of Treatment

Horney did not enunciate an explicit technique. The theory was still evolving; clinical application was limited; and it was, and still is felt that therapeutic techniques depend largely on the analyst's personality and must be adapted to the needs of each patient. Some guiding principles were formulated, however, and these have since been expanded with increased clinical experience.

The theory's redefinition of neurosis, its holistic-dynamic concept of self, and its growth-oriented approach required redefinition of the nature of the analytic process and its goals, with some practical implications, as follows.

With less attention to isolated symptoms, symptom relief is no longer a primary therapeutic goal of the analyst: a decrease in underlying symptom-producing conflictual elements will improve symptoms. The patient, however, seldom wishes basic personality change; this is too frightening at first. He wants to remove symptoms and difficulties but maintain the status quo.

Nor is social adjustment a therapeutic goal. Viewed psychologically, it often embraces compulsive conformity with little regard for the real self. The apparently well adjusted “successful” neurotic who actually lives a life of “quiet desperation” is the antithesis of the goal of greater self-realization.

The concept of “curing” neurosis makes no sense, since past development cannot be undone. But removal of stifling, distorting influences allows growth potentials to expand; in effect, the neurotic outgrows the neurosis. The aim is movement toward self-realization, rather than attainment to a specific degree of a certain kind of healthy attitude. The constructive must outweigh the obstructive. This goal is dynamic, relative, and qualitative, rather than fixed, absolute, or quantitative.

Neurosis is a self-perpetuating process, motivated by needs to maintain a distorted unconscious form of personality in order to gain a degree of unity and identity; it is not a simple repetition of infantile attitudes. Emphasis in therapy is on the present, placing recall in a different light. Childhood is important for

understanding of the formation of the neurosis and following changes in character structure and neurotic solutions as encompassed in the adult personality. Nevertheless, recovery of childhood memories is not a primary therapeutic goal but merely helps to expand awareness of current emotional experience as experienced in the past. Present experiencing permits past recall; past recall does not determine present experiencing.

Knowledge by the analyst of the patient's personality, and what is occurring dynamically therein at every moment, is essential.

To make conscious that which is unconscious is still a basic goal. Conscious knowledge must include not only information, but total awareness of inner happenings—past and present feelings and attitudes—now and in all their ramifications, as they affect the person's life and being, and as they affect others.

Gross movements during analysis take three forms: disillusionment, reorientation, and mobilization of constructive forces. These cannot be easily separated and usually occur to some extent at the same time. The first predominates at the beginning, the last toward the end.

Therapeutic techniques. Technique consists of optimal ways and means of applying these principles to produce the greatest possible progress toward these goals. Setting short term goals is as important as setting long term ones, and sometimes more so, depending on the patient's condition. Immediate goals might be simply to create a supportive relationship with another interested human being to hold the patient's personality together, if imminent disintegration, panic, or psychotic break threatens; to go along with or even reinforce some neurotic goals in order to strengthen motivation for continued analytic work (particularly important for adolescents); to define and emphasize constructive assets (although doing this too early may be ineffective or even unfavorable); or simply to educate the patient as to what constitutes analytic work.

A formal distinction between analysis and therapy was never clearly spelled out in the context of the Horney theory. Horney used the terms synonymously, often as psychoanalytic therapy. "Brief" psychotherapies directed at symptom relief or social adjustment are held to be of limited and temporary value only. Brief psychoanalysis with a predetermined time limit, intended to stimulate the patient's efforts, has been found ineffective in producing greater change faster. In fact, change may often be due to neurotic "shoulds," leading to intensified pride in achievement of spurious success.

Whether the treatment can be termed analysis is not determined by formal rules such as daily sessions, use of the couch, or the number of years the patient remains in treatment. Nor is it contradicted by use of short term goals, since these temporary strategic

therapeutic maneuvers may be preparation for, or part of further analysis.

Use of the couch. This is not essential; the seated vis-a-vis position may be equally, or more effective. It should be the patient's choice; and, eventually, he should feel free to use either. However, the choice may have healthy or neurotic implications for both patient and analyst and serves as the basis for analyzing attitudes. For example, the patient may choose the face-to-face position because he depends on the reactions of others, seeks approval or closeness, or wants to dominate the analyst by staring him down. On the positive side, facing the patient may provide the analyst with a better means of observation. Lying on the couch may be experienced by the patient as submission, humiliation at being lower (i.e., inferior), having to do what he should, exposing himself, being distant or sexually vulnerable, or losing control. It can serve the patient positively by permitting greater attention to his feelings without distraction.

Frequency of sessions. Frequency of sessions is another variable. Once weekly is usually inadequate, since the time lapse between sessions allows for dilution of emotional experiences and loss of continuity. Three times a week is usually optimal, though this may be increased if anxiety demands it. Some patients may make more progress on a once-weekly schedule than others do who are seen three times a week.

Fees. Requiring the patient to pay an adequate fee and assume responsibility for broken appointments is essential, not necessarily because of the feelings of sacrifice engendered but to indicate the value of the time, effort, service, and responsibility. Attitudes about payment must be analyzed as an aspect of general handling of money, or an expression of the patient's feelings toward the analyst. Compulsive promptness or lateness of payment, forgetting whether payment is to be made on a session or monthly basis, handing it to the analyst obviously, or mailing it unobtrusively can be indices of attitudes of compliance, resistance, perfectionism, claims for special treatment, needs for distance, etc.

Free association. Free association is desirable but not essential. It does not imply uttering everything that comes to mind, as classically stated, but refers to uncensored, spontaneous reporting of all inner experiences (sensations, feelings, thoughts, dreams, etc.), at the same time that attention is directed on such productions. This is seldom done early in analysis, since neurotic tendencies are implicated in speech, and spontaneity and involvement with self are impaired. Speech may be defensive (rambling), or combined with compulsive intellectualism (use of logic and reasoning). Freely speaking may be experienced as "letting go," giving up control, closeness to the unconscious—and, therefore, may be threatening. As analysis proceeds, however, the capacity for free association usually increases.

The analytic situation is a cooperative process of interrelatedness, functional in that its purpose is working, in which the analyst carries the greater responsibility. It is a constantly changing relationship, each partner influencing and reacting to the other. The patient's attitudes toward the analyst involve more than transference of child-parent attitudes. The analyst is experienced in complex ways, derived from the patient's unique neurotic needs, expectations, and claims, which change at different times. The analyst may be felt as a loving or revered god or magician; as a punitive judge; as a confessor, teacher, competitor, tool, co-worker, or friend. Each attitude carries unconscious claims for change through the magic clue or the analyst's power, i.e., without personal effort, or through absolution, i.e., learning a lesson or being a good patient.

Analyst's role (counter-transference). The analyst plays an active role in the treatment, in the sense of emotional participation, in contrast to the detached, evaluating observer with the classical "mirror" function. There is a repeated emotional movement between the patient and the analyst which requires understanding, tolerance, and compassion, despite disagreement. Attention must be comprehensive, wholehearted, feelingful, and productive. The analyst's reactive feelings can help indicate unconscious maneuvers of the patient. However, he should be able to distinguish his own neurotic residual feelings. Such neurotic remnants as arrogance and pride, the need to dominate or be self-effacing, to please or avoid friction, or his own detachment may cause him not only to select particular patients, but also to overlook or have difficulty in handling those attitudes in his patients which are present in himself. His relationship with the patient will be governed by his relationships with others.

The analyst's help may take many forms. His mere presence provides general human help. His interest, willingness to understand, faith in possibilities, acceptance of weakness or hostility without criticism or recrimination, and firmness against cajolery furnish a kind of relationship different from any the patient has previously experienced. The analyst attempts in various ways to encourage the patient's interest and involvement. He tries to stimulate awareness of neurotic trends, their intensity and extensity, mutual contradictoriness and destructive potential, their nature as immediate feelings and as past experiences. He utilizes intuitive impressions and detailed observations, notes contradictions between statements, attitudes, values, patterns of the analysis from moment to moment, hour to hour, daily, weekly, and yearly. He notes themes communicated symbolically at various levels of the patient's associations (reality; interpersonal, including analytic; and intrapsychic). He employs dreams as indicators of uncon-

scious processes. All of these may at times be conveyed as interpretations.

Interpretations. The analyst's interpretations may stimulate, uncover, focus attention, summarize, repeat, express understanding, and serve as background. Their spirit should be questioning and tentative, intended to stimulate. They may be explicit remarks or implicit signs: grunts, smiles, encouraging gestures. For maximal progress, regardless of anxiety or relief induced, they should be relevant to the most significant issue consciously or unconsciously raised by the patient; meaningful, according to his present condition and traits; timely, for constructive use at the moment. Positive patient reactions include taking the interpretation seriously, finding it pertinent, working further with it. Negative reactions might be lack of understanding, undue anxiety or hostility, pseudo-acceptance without real assimilation, or blockages.

Resistance. Within the traditional concept, three forms of resistance are described in the context of the Horney theory. Forces interfering with the drive toward self-realization (including the neurosis itself) are retarding forces. However, such obstructive forces need not prevent progress; a neurotic need to know everything can be an incentive to work at something. Such obstructive forces are manifested as defenses, evident in life, but more so in analysis when the patient is under attack. The constant question is: "What is he defending, and what is he defending against?" These are the characterological trends and attitudes of the neurotic structure. Specific manifestations of these defenses, arising when they are threatened, are called blockages. They may be personal or impersonal; expressed against self, analyst, or others; passive or active; acute (such as use of alcohol or drugs, silence, listlessness, forgetting, or "acute negative therapeutic reaction") or chronic (lessening of curiosity about self, inertia, increased unconscious dishonesty through denial, rationalization, vagueness, complaints about lack of progress).

Dreams. Dreams are a primary tool for furthering analytic insight, to extend beyond just taking into account latent symbolic meanings. The first dream related in the analysis, whether a present or a past recurrent one, is crucially significant. It is the purest, tersest, and most meaningful, often expressing the patient's entire personality structure and attitudes toward life and the analysis; it can seldom be interpreted effectively early in treatment. The form of dreams is important; they may be abbreviated or detailed, disorganized or structured, close to or far from reality, static or full of movement. The rhythm of the dreaming pattern—rare, frequent, cyclic—indicates psychic activity; why the dream has been presented *now* should be considered. Series of dreams may indicate evolution of some trend or psychic movement. Attitudes toward dreams—actively relating them to self, recall at beginning or end of hour, good recall or

forgetting, verbal or written, etc.—indicate attitudes toward the unconscious. Content may show symbolic meanings not only as object symbols, but as representations of attitudes, conflict, solutions, directions of movement, active or observer involvement, relationships with others, degree of relatedness (dreams within dreams, movies), etc.

Limitations of therapy. The limitations of Horney therapy are determined by the goals, the degree to which any patient can avail himself of it, and by lack of experience of its practitioners with specific diagnostic conditions. It is long term therapy requiring much time and money, thus it is limited in the number it can reach, although low cost clinics and group analysis are increasing this number. An overwhelmingly unfavorable past or present environment may limit the extent of change. A certain capacity for psychological thinking and awareness is required, although this is relative. Also favorable are a certain moral toughness, a tolerance for anxiety or psychic pain, ability to stay with a problem, a basic desire to change, and a certain intelligence and imagination. Absence of these qualities is limiting. Advanced age is a relative limitation, rigidity of attitude and behavior being more important than chronological age. Use of this therapy with children is still limited; further experience is needed. Application to psychotics and sociopathic or acting out personalities is largely unexplored, with clinical effectiveness demonstrated in a limited number of cases. Some aspects of certain specific conditions, such as sexual perversions or psychosomatic diseases, have not yet been satisfactorily explained in the holistic framework.

Current Perspectives

Given these limitations, as well as its already proven empirical value for patients amenable to analytic treatment, what is the future of this theory? On one hand, its application seems to be growing as the number of its practitioners increases and further usage is explored experimentally. It can be applied to conditions hitherto considered to have a poor prognosis, such as certain forms of psychosis, and adolescent syndromes. One indication of its value lies in the number of its ideas being adopted (and adapted) by classical psychoanalysis (usually without credit being given to Horney), such as the synthesizing ego functions and the significance of pride in neurosis (Hartmann); the expanded notion of neurotic polarities in conflict, leading to further conflict (Kubie); the re-evaluation of narcissism and the ego ideal (A. Reich, Arlow); the concept of a "working relationship" in analysis; and others.

On the other hand, in its present state Horney theory is not the final answer to our understanding of psychopathology, and it will require continued clarification and modification to increase its applicability, i.e., to particular mental conditions, such as the childhood behavior disorders and certain forms

of psychosis, to particular types of patients, such as the elderly, to lower socioeconomic groups, to the mentally retarded. It must be refined for application to newer settings, such as the clinic, for use with the heterogeneous group, the family, and for usage in combination with psychotropic drugs.

7.3 HARRY STACK SULLIVAN

LEON SALZMAN, M.D.

Introduction

Harry Stack Sullivan received his training in psychiatry during the early years of Freud's profound influence on American psychiatry. However, he did not go to Vienna for his psychoanalytic experience and training, as did so many of his colleagues. Instead, he worked in the United States with Adolf Meyer at Johns Hopkins, at the Sheppard Pratt Hospital in Towson, Maryland, and with William Alanson White at St. Elizabeth's Hospital in Washington, D. C. He was a founder and charter member of the Washington Psychoanalytic Society, and founder of the Washington School of Psychiatry. Both his analytic training and his personal analysis were in the classical tradition.

Sullivan made basic and significant contributions to psychodynamic theory and to the theory of mental disorders, which emphasized the cultural matrix of personality development.

The particular direction and emphasis of these contributions derived from his close association with social scientists, such as Ruth Benedict, Margaret

Mead, Edward Sapir, Leonard Cottrell, and Harold Lasswell, and with culturally oriented colleagues, such as Erich Fromm and Karen Horney. In brief, Sullivan worked closely with a group of psychoanalysts and social psychologists who were moving away from the classical psychoanalytic theories because of the biological and instinctual bias of those theories.

Historical background. Freud believed that man developed out of a matrix of instinctual forces which needed to be restrained and inhibited when confronted by the external world. According to this instinctivist psychology, then, man was viewed as an animal, overwhelmed by inner forces which he must repress or restructure in order to survive as a social being. The focus of study, therefore, was directed primarily toward the elucidation of these inner pressures which were topographically located in the id. The unconscious, as a reservoir of id forces and repressed impulses, was the source of great interest in psychoanalytic theory and therapy. Freud's system was called an id psychology, in contrast to later theories, which were centered on the psychology of the ego.

There were serious objections to Freud's psychoanalytic theories from the beginning, particularly to the sexual nature of the libido. These disagreements ultimately produced dissensions in the psychoanalytic movement. In the early 1900's, and especially during the period of mass exodus of psychoanalysts to the United States in the 1930's, there was evidence of growing dissatisfaction with Freud's instinct theory, and increasing recognition of the significance of ego factors in man's psychology.

These European psychoanalysts, particularly Karen Horney, Erich Fromm, Sandor Rado, and Franz Alexander, were exposed to a new culture, where the predominant values and ethics differed from those they had known in Europe. Some of Freud's theories which were presumed to have universal application did not seem to be as significant in the American scene as they were in Germany or in the Austro-Hungarian culture. This raised many new questions about the role of culture in personality development. The effect of culture, as opposed to instinct, took an increasingly prominent role in personality theory. The ubiquity of many of the variables in human development, which had been considered biologically ordained, were examined anew in the light of the influence of the social, political, and economic factors in man's growth. The Oedipus complex, for example, which Freud and his followers believed was inherited and biologically innate could be viewed as a potential development which might be manifested if the social structure of the family or the community stimulated attachments to the stronger members of the household. In other cases, subtle or overt sexually seductive behavior on the part of the child's parents might constitute a precipitating factor in the emergence of this phenomena. In any event, the Oedipus complex could not be viewed as innately present in all in-

dividuals regardless of their experience with their parents or the social structure of their environment.

In addition, the climate of scientific philosophizing was vastly altered in the 1900's by the formulations of electromagnetic theory and Einstein's theory of relativity. Freud had formulated his theories on the basis of the prevailing scientific model of the 19th century, i.e., the mechanical, physical model, represented by hydraulics and energy mechanics. And this was entirely appropriate for the late 1800's, before wave and quantum theory were elaborated to explain the physical world. However, the deficiencies of the mechanical model became glaringly apparent in the 1900's, when the principles of interaction, transactional theory, relativity, and the field theory concepts tended to emphasize the limitations of the mechanical model for the study of the behavior of particles, as well as man.

Sullivan's Scientific Orientation

This was the setting for Sullivan's intellectual development. The ultimate elaboration of his theories of personality within an "interpersonal" framework reflected the strong influence of his social scientist colleagues and his talent and interest in science in general. More specifically, Sullivan was dissatisfied with those psychological theories which depended upon extensive extrapolations from hypotheses which themselves could not be tested. He was particularly impatient with those psychoanalytic concepts which could not be validated because they were based on experiences which were beyond recall or because they required prior acceptance of certain variables, such as the aggressive or death instinct, as universal human attributes. Consequently, he insisted on formulating his concepts entirely from observable data.

Methodology. For example, instead of postulating a maternal instinct to explain the dominating interest of a mother in her child, or the desire of a woman to have children, Sullivan hypothesized that the tension of the infant's needs stimulate anxiety in the mother, which is manifested as tenderness and results in the care and attention that the infant requires. This proposition, which he called the "tenderness postulate," is described later on. It is possible to test the validity of this formulation by studying the effect of the needs of the infant on all adults in his immediate environment and then determining whether the biological mother is actually more involved with the infant than any other person or whether anyone who is capable of tenderness is not equally affected by the helplessness of the infant. Unlike the conception of a maternal instinct, which presupposes an innate interest and tenderness toward one's offspring, this proposition examines the phenomenon of motherhood and tenderness as an interpersonal development, dependent on the stimulation of anxiety in one person by the needs of another.

Similarly, Freud's assumption of an innate aggres-

siveness, known as an aggressive instinct, predetermines the observation and identification of a piece of behavior, since it is assumed that aggressive behavior is universally present. Sullivan suggested that the notion of an aggressive instinct be put aside and human behavior simply observed. It may be that evidences of aggressiveness will be discovered, but one can then proceed to explore the conditions under which it was produced, whether it is universally present as a primary phenomenon, or whether it is secondarily provoked by the behavior of another person. This is a critical matter and has been the subject of a great number of genetic, biological, and anthropological studies. The developmental child studies of Piaget, Gesell, and others strongly suggest that aggression is a secondary phenomenon rather than an innate one.

In this sense Sullivan limited his concepts to formulations which were capable of being tested and either validated or disproven. The prior assumption of an Oedipus complex or an aggressive instinct does not permit the investigator to observe human behavior objectively and without prejudice. Consequently, when one begins by assuming the existence of an aggressive instinct, and then aggression is noted in a child, this becomes evidence that such an instinct does indeed exist and only needs to be identified. If, on the other hand, one does not begin with this assumption, then one is free to speculate as to what elicited this specific reaction, rather than other possible reactions, and what circumstances are likely to produce an aggressive reaction rather than some other type of response.

Many of the early psychoanalytic hypotheses grew out of speculations and global interpretations based on a few intensive analytic studies. Data was then accumulated to affirm these hypotheses. Thus, once the notion of an innate Oedipus complex was proposed, the absence of confirmatory data was described as "denial of its presence," while the presence of data to confirm it was accepted at its face value. In contrast to this approach, Sullivan suggested that if the investigator begins afresh, without previous preconceptions, he will find the Oedipus complex present in a great many individuals. However, Sullivan insisted that the investigator would also find it absent in many individuals. Ideally, the investigator would then be stimulated to identify the factors which might account for its presence in one person and not in another, and this would greatly advance the understanding of this phenomenon.

In fact, the situation prevails in large areas of psychoanalytic theory, where present knowledge does not justify reified concepts. This can be demonstrated most succinctly in some of the prevailing notions on the psychology of the female. For example, the concept of penis envy states that the female not only experiences the absence of a penis as a loss and a denial, but actively envies the male in this respect.

This concept is an outgrowth of Freud's notion of the primacy of the male. Accordingly, a great deal of activity in the female, such as competitiveness with the male in occupational or aesthetic pursuits, or aggressive striving for status and esteem in so-called male areas of interest is automatically labeled penis envy and is derogated or viewed as abnormal if it extends beyond certain limits. However, if the female is studied without prefixed notions as to the components of her behavior, one might conclude that her activity derives from many sources, some of which are far removed from sexual envy. Her competitiveness or aggressive strivings might be a reaction to cultural restrictions and prejudices, as well as the result of a natural striving for achievement. Feminine interest in male pursuits can be viewed as an unwillingness to accept such distinctions which, after all, have been categorized in this way by the male. Sullivan did not allow such "established" concepts about the female to intrude upon his investigations; instead, he tried to study the origins of behavior in the context of a specific situation and within the framework of his subject's idiosyncratic personal history.

Clearly, when the observation and examination of data are guided by open-ended hypotheses which are capable of being proved or disproved, this is conducive to a more scientific approach to the study of human behavior. Sullivan's views generally encouraged such an approach.

Area of investigation. Sullivan defined psychiatry as the study of interpersonal relations which were manifest in observable behavior of individuals. While he had great interest in what transpired on the "inside" of an individual, he felt that the individual could be studied only in terms of his interaction with others. Thus, the main focus for Sullivan's study of man was man's transactions with others, and particularly the activity that transpired between them. The field of operation, or how one person behaved toward another, and how each person's behavior was affected by the behavior (both overt and covert) of the other, as well as the subjective experiences of each, was a valuable area of study. While these phenomena could be studied only with difficulty outside of the therapeutic situation, the process was greatly enhanced when the therapist was one of the participants, for then psychiatry became a transaction between the therapist, who was a participant-observer, and a client whose living was disturbed or disordered. For this reason, Sullivan's theories and concepts tended to be more operational and capable of being tested outside of a subjective framework. Their validity as a tool for scientific investigation was further enhanced by the fact that he took great pains to define his terms and to limit the boundaries of their application.

Not only were Sullivan's theories congenial to social scientists, because they stayed close to the traditional scientific methodology; they were also of interdisciplinary value because his emphasis on the

field rather than the individual gave greater prominence to the social and cultural context in which personality develops. This emphasis on the interpersonal, and a reliance only on data which are observable through gesture, verbalization, sign, or other communicative devices, has constituted the strength of his theoretical constructs, but it has also been a source of criticism: Sullivan felt that there was no way to study the individual's purely private, uncommunicated thoughts and fantasies. Therefore, it has been suggested that he neglected the uniquely personal elements of an individual's personality. While this is certainly true to a limited extent, the fact is that Sullivan believed that such study was the province of literature, rather than psychiatry. Thus, he justified his "neglect" of individuation as a proper concern and goal of human maturation, by insisting that psychiatry must deal with those human characteristics that were shared and communicated to others. He felt that these were fundamental issues involved in psychiatric disorders. Consequently, he was the paradigm of the ego psychologist. He saw man as an animal, biologically bound, whose potentialities and possibilities were determined by his culture. In summary, then, Sullivan defined psychiatry as the study of biological and conditioning processes which occur in situations in which the psychiatrist functions as participant-observer, the unit of study being the interpersonal situation.

Basic Theoretical Concepts

Sullivan formulated four basic postulates as the foundation for all his theories.

Biological postulate. This stated that man, as an animal, differs from all other animals in his cultural interdependence. Thus, man's functioning within his cultural matrix differs from the herd behavior which is characteristic of some animals; nor is the organization of human society patterned on the colonies created by ants and bees. These forms of communal living are instinctually derived, not volitionally determined. In contrast, man's cultural development is a function of his psychological, as well as his physiological dependence. More specifically, it stems from his growing capacity for tenderness, from his ability to develop an interest in another human being which is equal to his interest in himself.

Man's essentially human mode of functioning. Sullivan maintained that "man is more simply human than otherwise." This postulate implies that man, in the performance of his most diverse activities, is still closer to the human mode of functioning than to that of animals. It emphasizes the basic similarity between the most extreme behavior and the human mode of behavior, rather than resorting to analogous animal behavior to explain atypical human behavior. It tends thereby to encourage more simple explanations for complicated distortions of behavior, without evoking unnecessary or unsupported hypotheses de-

rived from myth or instinctual explanations. This does not obviate the value of animal studies, or comparisons between animal and human behavior. It only refines and restricts the application of the findings derived from such studies; they are useful only after the explanations deriving from our present knowledge of man have proven inadequate.

Significance of anxiety. This refers to the central role of anxiety in human development. It emphasizes the presence of anxiety, to varying degrees, in all human functioning, but postulates the impossibility of absolute states of anxiety, and, concomitantly, of absolute states of euphoria. The varying amounts of anxiety present in an individual will, in turn, determine his variable state of euphoria.

Tenderness postulate. This basic theoretical formulation has its roots in Sullivan's theories. It is an attempt to conceive of tenderness, in all its various manifestations, as an interpersonal development, rather than as an innate feeling present in the form of an instinct or a God-given virtue. Thus Sullivan states that "the activity of an infant which arises from the tension of his needs produces tension in the mothering one which is felt by her as tenderness." At first glance, this would seem to contradict another of Sullivan's concepts, i.e., that tension evokes anxiety which, in turn, necessitates the creation of defenses against the breakthrough of that anxiety.

In this instance, however, the anxiety which the tension of the infant's needs evokes in the mother is experienced by her as tenderness.

Thus, in this postulate Sullivan recognizes that anxiety does not always exert a disintegrating effect; nor does it always constitute an obstacle in interpersonal functioning. The needs of the infant, who is utterly dependent, will evoke a response of tenderness rather than irritation. Anxiety, then, can be viewed as a creative force, as well as an inevitable accompaniment of human growth. And within this framework, the development of tenderness can be visualized as a response to the need of others without exploitative or selfish motives. As pointed out earlier, this postulate is an excellent example of Sullivan's efforts to comprehend the intricacies of human attitudes and feelings as they emerge in the matrix of interpersonal relationships, rather than as innate tendencies.

The infant's need for tender concern, in addition to the fulfillment of his physiological needs, has been amply documented by the work of René Spitz, Margaret Ribble, Harry Harlow, and others. Usually, a maternal instinct is postulated to account for the mother's benevolence toward the infant. As mentioned earlier, Sullivan, in his disdain for instinctual explanations to account for global and complicated behavioral patterns, preferred to view the mother's impulse toward tenderness as a phenomenon aroused by the infant's needs. Moreover, this reaction to the tension of the infant is not confined to the infant's

biological mother; rather, the tension of the infant's biological needs may evoke a similar response in anyone else in the immediate life space of the infant. The caretaking individual reacts with tension, which manifests itself as behavior designed to meet the needs of the infant. This is described as tenderness and is the prototype of all tender activity in human behavior in which giving is the essential ingredient. As will be indicated in the following presentation, Sullivan's concepts of anxiety, love, hostility, etc. are all expressed in interpersonal equations, thereby eliminating instinctual, metaphysical, or theological presuppositions.

Goals of Human Behavior

All human beings have major goals which Sullivan called end states. The first goal is to fulfill the biological needs of the organism in terms of food, air, sex, etc. The second goal relates to man as an acculturated social being and involves those needs which go beyond the purely physiological necessities. These include the need for status, recognition, and a relationship with others. The first goal is called the need for satisfactions, and the second, the need for security.

Modes of need fulfillment (dynamisms). These needs are manifested as inner tensions, and the characteristic ways in which the individual strives to fulfill them are called dynamisms. The dynamism is the constellation of complex movements which constitute the specific activity designed to fulfill or overcome a need, whether it is a need for food, sex, or self-esteem. The infant's cry, for example, is the simple dynamism used to fulfill his multiple needs. As his needs become more complex, the dynamisms he employs become more complicated and varied. Most dynamisms serve to satisfy the basic needs of the individual, but the self-dynamism or self-system develops as a result of, and in response to, the basic anxiety engendered by these primitive needs. This is the personality structure which permits the satisfaction of more complex needs at later stages of development.

The dynamism involves a bodily zone such as the mouth or the genitals, but in the case of the self-dynamism, no bodily zone is involved. The presence of a particular bodily aperture in the dynamism gives it a special coloring. This concept of Sullivan's bears some similarity to Freud's theory of the sexual phases of psychosexual development, but there are also some marked differences. Freud considered these bodily zones to be the central determinant of behavior at specific phases of development. For example, for Freud, the oral phase of psychosexual development evolved around the biological qualities of the mouth as a receiving, sucking, biting aperture. These apertures were important to Sullivan too, but because they were the areas through which the individual established interpersonal contact. Thus the infant, whose biological needs are paramount and to whom

the mouth plays a crucial role as a vehicle for the satisfaction of his nutritional needs, tends to relate to the environment almost exclusively on an oral level. Therefore, the glottis and vocal chords, as well as the mouth, and a wide variety of sensory and tactile impressions, color the infant's experiences. It was this factor, rather than the accumulation of libido in the oral area, which made the oral aperture a significant area of personality development.

When a dynamism manages to achieve or fulfill a particular need, the tension of the need is removed, and the situation is described as having been integrated, satisfied, or resolved. However, many needs are either unfulfilled or only partially fulfilled by the dynamism. The success of a dynamism in fulfilling a need completely, particularly in regard to the need for security, is frequently interrupted by the presence or development of anxiety in the course of the operation of the dynamism. This is described as a disintegrated situation, in contrast to an integrated situation in which a need is fulfilled. Because anxiety can be a dysjunctive or disintegrative force when it interferes with the fulfillment of the individual's needs, Sullivan accorded it a central role in human psychological development and its vicissitudes.

Need for satisfaction. The failure to fulfill a biological need is not necessarily accompanied by anxiety, although there will be some associated somatic distress, such as hunger, thirst, or cold. While these sensations may propel the organism to action, they do not necessarily result in anxiety. It is primarily the failure to fulfill one's security needs that evokes anxiety. Furthermore, anxiety may be either the cause or the result of the failure to fulfill the need for security. However, the pursuit of biological satisfactions and the pursuit of security are intermingled and cannot be isolated in practice.

Need for security. In an affluent society, man's tensions are almost exclusively related to his need for security, which can be satisfied only through meaningful interpersonal relationships. If an individual has notable success in fulfilling both his biological and psychological needs, and he experiences a minimum of disintegrating situations, he will feel only a minimum of anxiety. The increasing power and confidence he feels with regard to his security will give rise to a feeling which Sullivan called self-esteem. A sufficient, albeit minimal amount of self-esteem is required to deal with the realistic feelings of powerlessness and helplessness which are evoked in man in the course of his lifetime. In more specific terms, self-esteem is directly related to the amount of anxiety the individual experiences in his daily life and his capacity to deal with it effectively. Therefore, mental illness, or personality disintegration, that results from excessive anxiety is intimately linked to the lack of self-esteem and self-regard, and the feeling of powerlessness in interpersonal activities. Just as there are no absolute states of freedom from anx-

iety or euphoria, no individual is totally devoid of self-esteem. Massive feelings of anxiety such as panic do occur, but these situations are fleeting and never permanent. Ordinarily, the degree of anxiety present in an individual extends over a broad continuum and is consistent with variations in his mental health or illness.

Modes of Experiencing

Sullivan's personality theory takes account of the role of cognition and learning in human development. Consequently, he distinguished between various modes of experiencing, and their influence on intellectual and emotional development. These modes of experiencing, which depend upon the development of cerebral capacities, as well as other physiological skills, permit the development of such psychological functions as differentiation, symbol formation, and other complex intellectual processes to occur. Since much learning occurs in an interpersonal context, the individual's capacity to comprehend such relationships and his mode of experiencing them will influence his learning capacity.

Prototaxic mode of experiencing. This is the earliest mode of experiencing and consists of raw, undifferentiated, momentary states. There is no connection between experience and the feelings or ideas within or outside oneself; consequently, such experiences seem to have cosmic and universal connections. They have no continuity of past with present or future and appear to be isolated and incomprehensible. Such experiencing is characteristic of infancy and occurs in mental illness, particularly schizophrenia.

Parataxic mode. In this mode, events appear to be causally related because of temporal relationships and serial connections. However, there need not be any logical relationships. Consequently, since cause is determined by temporal relationships, the opportunities for distortion are manifold. For example, the child who notices that his mother is angry when he enters her room may attribute the anger to his appearance, rather than to an earlier dispute she had with her husband. This kind of distorted thinking, which Sullivan calls parataxic, is not uncommon in human functioning, and it is an essential ingredient in the thinking of the paranoid in whom false referential interpretations arouse feelings of malevolence or danger.

Serial thinking of this kind is a stage in the development of logical thinking and is not, in itself, evidence of mental disorder, although it plays such a significant role in the maintenance of suspicious, superstitious, autistic, and paranoid thinking.

Syntactic or logical mode. In this type of experiencing, events are related through logical or rational thinking. It is this experience that has consensual validation and follows a logical train of deductions. Consequently, it is the most mature type of experiencing and represents the highest cognitive capacity

of which man is capable. To illustrate, if a group of people begin to laugh when the individual capable of logical thinking enters a room, he looks about and discovers that someone has just finished telling a funny story. In contrast, under similar circumstances, the individual whose mode of experience is governed by parataxic thinking would immediately conclude that the laughter had been provoked by his entrance. Obviously, the capacity for syntactic thinking requires comfortable amounts of self-esteem.

These three types of experiencing occur side by side in all individuals, and the process of maturation rarely achieves the level where experiencing follows the syntactic mode exclusively. Typically, most human beings function on all three levels, with a minimal amount of experiencing in the prototaxic mode. The neuroses and psychoses involve a great deal of perceptual distortion, initiated by the nonlogical, more primitive modes of experiencing. Viewed in this light, the cognitive distortions in mental illness appear more comprehensible and less alien to the functioning of "normal" people with more adequate adjustment.

Sullivan also emphasized the importance of foresight, which involves not only consideration of the future, but a consideration of the past in relation to the present and the future. Sullivan held that anxiety might seriously interfere with the crucial role of foresight in human behavior and, concomitantly, interrupt the learning process.

Learning

While Freud conceived of learning almost entirely in terms of the pain-pleasure principle, Sullivan amplified its role in personality development. He placed particular emphasis on learning as a way of minimizing anxiety, and the ultimate development of a self-system consisting of techniques for avoiding anxiety. In addition, he described a number of factors which are essential to the learning process, such as empathy, self-sentient activity, trial and error, reward and punishment, learning through imitation, and, ultimately, deduction and conceptualization. Learning, he maintained, was accelerated by lowering the anxiety gradient. On the other hand, however, he recognized that the initiation and motivation of the learning process depended on the presence of a certain amount of anxiety. Sullivan's description of self-sentient activity was a particular contribution to learning theory. This enables the individual to develop techniques for alleviating anxiety, boredom, or states of deficiency, through activities in which he is not only the provider, but the recipient of satisfaction. This is true of masturbation or intellectual pursuits, in which the rewards are the outcome of one's own initiative and action. However, this type of learning can be accelerated or impeded by cultural values and attitudes toward activity which provides pleasure through one's own capacities. For ex-

ample, some bodily manipulations are approved, while others, such as genital or anal manipulations, are strongly condemned. This is true of certain intellectual pursuits as well. As a result, exploratory activity may be abandoned, and interest in one's body and certain cultural areas cease. Such reactions may produce serious personality complications in later life.

Sullivan's interest in the individual as he becomes acculturated in the human environment encouraged his explorations in learning theory, which is currently playing an important role in the therapy of mental disorders.

Anxiety

Anxiety is the focal issue in personality development for the neo-Freudians, as it was for Freud himself. Like all other concepts developed by Sullivan, anxiety was seen as an interpersonal phenomenon and was described as the response to the feelings of disapproval from a significant adult. Thus, it can *only* occur in an interpersonal context, even if the other person is not real, but a phantasied or eidetic image. The feeling that he is disapproved of can be communicated to and interpreted by the individual in a variety of ways, or it can be falsely interpreted, as would be the case in prototaxic or parataxic experiencing. In any event, since anxiety is a most distressing feeling and may be accompanied by a variety of somatic symptoms, as well as psychological feelings of impending doom, it cannot be tolerated for long and must be dealt with.

In large measure, Sullivan views personality development as a process of learning to handle anxiety by the use of adaptive maneuvers and defensive techniques. Since anxiety stems from the feeling that one's security needs are threatened, essentially, these patterns are techniques for achieving security by gaining approval from significant people. They become incorporated into the self-system, which forms the matrix of the personality structure of the individual. When anxiety is widespread, the individual attempts to limit the opportunities for the further development of anxiety by restricting his functioning to familiar, well established patterns of activity. He avoids new and novel experiences, in order to reduce the risks of living. But in doing so, he also reduces his spontaneous activity and is limited to situations where he can predict the consequences of his actions.

In brief, the self-system may restrict and rigidly proscribe the activities of the individual and thereby interfere with learning and motivation. Thus, in attempting to achieve security, the self-system may actually make the individual more vulnerable. For example, in the process of maturation, the individual may develop and incorporate into his self-system a pattern of selective inattention. Selective inattention may enable the individual to focus on the relevant, and to dismiss the irrelevant. However, if it is em-

ployed extensively, it can become a technique which will enable him to overlook any instances of behavior that may be "upsetting" i.e., anxiety-provoking. In this way, a potentially valuable technique can become destructive and incapacitating if it is used too widely: it can restrict one's horizons and cut off opportunities for learning.

Sullivan's concept of anxiety is particularly valuable in the therapy of mental disorders. The presence of anxiety serves as a beacon, to facilitate identification of the patient's problem, and it highlights those elements of the patient's personality which he feels will meet with the therapist's disapproval. Exploration of the anxiety experience is the most fruitful and direct way of uncovering repressions and dissociations. However, as mentioned earlier, while anxiety usually carries a negative connotation, Sullivan pointed out that it may also constitute a positive force, propelling the individual toward learning new techniques and devices for dealing with it.

Role of Sex

In contrast to Freud, who maintained that sexual factors were of major significance from the earliest years, Sullivan felt that sex played its most significant role in the later developmental stages. This is not to devalue its significance in human affairs, since Sullivan was very cognizant of its intense capacity for initiating and sponsoring intimacy and relationship. However, he did not assign it a leading role in motivating the developmental processes, nor did he view sex as the primary source of neurotic or psychotic disturbance. In his view, sex entered the human scene during adolescence, when it served an essential function in integrating interpersonal, heterosexual intimacy. In view of the cultural attitudes and prejudices and the powerful effect of anxiety on sexual performance, the earlier experience of the individual may produce serious obstacles in the development of adequate sexual behavior. In this way he accounted for homosexuality and other sexual disorders as symptoms, rather than causes, of personality disorders. Phobic attitude toward the genitals or difficulties in sexual identification can prejudice the sexual performance in later life. Like other post-Freudian psychologists, Sullivan viewed lust as significant, but not central in man's behavior. He saw it as a biological function which has special capacities for pleasure. Because it requires physical intimacy, it can serve as the stage on which many other human needs are fulfilled.

Stages of Personality Development

Personality is a collection of processes which occur as an outgrowth of interpersonal experiences, rather than the unfolding of intrapsychic forces. For Sullivan, personality manifests itself only in relation to other human beings. It is embodied in the self-sys-

tem, and Sullivan described its development in terms of epochs which reflect the changes in the interpersonal environment of the maturing human being. He described six stages, which were subsequently condensed into five. (1) Infancy. From birth to the beginning of language (1½ to 2 years). (2) Childhood. From language to the need for compeers (2 to 5 years). (3) Juvenile era. From the need for compeers and the beginnings of formal education to preadolescence (5 to 8 or 9 years). (4) Preadolescence. From the beginning of the capacity for intimate relationships with peers of the same sex until genital maturity. (5) Adolescence. From the patterning of genital behavior with the opposite sex until maturity.

Infancy. This period of development is characterized by utter helplessness and dependence on the benevolence of other humans, particularly the mothering person. The infant's cry and his capacity to arouse tenderness in others are his only tools for satisfying his needs. The oral zone is the area of interaction with the world, and the development of feelings of security and self-esteem depend entirely upon the infant's capacity to fulfill his needs.

Anxiety makes its first appearance during this period as a result of the infant's failure to achieve satisfaction of his primary needs. The infant also experiences feelings of security or anxiety through a process of empathy. And he learns some techniques for dealing with anxiety; these include implementing his cry or somnolent detachment or apathy to avoid the tension of needs which produce physiological disequilibrium (dehydration, etc.), or the psychological feeling of total rejection. The cry which achieves such magical results in infancy takes on special significance in later years in the form of language.

This epoch also marks the beginning of symbol formation and the recognition of signs, particularly the forbidding gestures from others, which warn the infant to refrain from those activities which provoke such gestures. Repeated experiences with these forbidding gestures enable the infant to determine in advance which behavior is acceptable and which is not. Thus, the beginnings of the self-system are recognizable in infancy. In addition, the infant begins to develop a set of concepts of himself, as well as of others. Some aspects of his behavior which meet with approval are considered to be part of the "good me" personification; those which stimulate anxiety and disapproval are considered to be part of the "bad me." Other items of behavior which produce marked reactions of loathing, shame, or intense rejection may become part of the "not me," which can be repressed and dissociated. These may ultimately come to play an important role in the later development of neurosis or psychosis. Since Sullivan felt that sex does not play a major role in the developmental process until the gonads have matured, these "not me" personifications do not necessarily involve sexual or libidinal

transgressions, in contrast to the pregenital repressions which Freud described in such detail. However, the cultural attitudes toward genital and anal manipulation may stimulate enough anxiety in the infant and toddler to produce an avoidance of these areas. Sullivan called this genital avoidance a primary genital phobia, which he subsumed under the "not me" personification.

As mentioned above, the self-system begins to develop in infancy and becomes a technique for avoiding anxiety. However, as it expands, it may tend to restrict further experience, if the potential for anxiety is too great. If the self-system becomes too restrictive, it may interfere with the necessary experimentation and risk-taking which are essential for growth and may seriously impair development in later epochs. The degree of anxiety and the defenses against it which develop in the earliest period of personality development will strongly influence the child's capacity to benefit from the experiences in later periods.

Ultimately, the individual's self, or ego, is made up of reflected appraisals which represent the views that others have of him. If others treat us with respect and tenderness, then we treat ourselves with respect and tenderness. If the individual is viewed by others in a critical or derogatory way, or if he believes that others think of him this way (although this may be a distortion in perception), his view of himself may be derogatory. However, the self-system is never completely rigid, and it does allow for alteration and change through correction by later experiences or therapeutic intervention.

In summary, the self-system, which Sullivan preferred to the term "personality," is a reflection not only of maternal and paternal attitudes, but of an accumulated set of experiences which begin in infancy and continue for a long period of time.

Infancy is a crucial stage of development; the outcome will depend on the nature of the infant's interpersonal relationships with benevolent or malevolent individuals. These relationships can produce the infant's first experiences of trust, faith, feelings of power and esteem, or they may leave the infant uneasy and uncertain, with feelings of powerlessness and helplessness. In infancy, most needs are satisfied automatically with a minimum of stress, and only occasionally is the satisfaction of these needs characterized by restraint or limitation. However, as verbal skills mature and the infant's capacity to comprehend the limits of the environment develops, he begins to experience denial and limitation. When the sphincters mature, training of the bowels and bladder takes place, and the cultural requirements of propitious eating and socializing are inaugurated. This ushers in the period of childhood.

Childhood. This is the period of acculturation, when the individual learns the mores of the particular culture to which he belongs. Depending upon the

amount of anxiety present in infancy and the security operations he develops to reduce and eliminate it, the child can benefit, or fail to benefit, from the experiences in this era. The development of sphincter control, eating and dressing habits, and behavior toward adults and other children are all dependent upon the child's self-esteem and his capacity to deal effectively with the parental figures. Since learning is associated with considerable anxiety (through reward and punishment), the self-system begins to expand very rapidly. The development of language and the capacity to sublimate, which permits one to retain unacceptable needs by transforming them into acceptable channels of satisfaction, begin to manifest themselves.

The problem of becoming educated into the requirements of one's culture is often extremely difficult, not only because of unfavorable experiences in infancy, but because of the contradictory demands of the culture. The experiences of fear and anger, and the value of obsessive verbalization, e.g., "I'm sorry," or "excuse me," begin to manifest themselves. Concurrently, the need to hold firm by negative or resistive activities also becomes apparent. Willful activity, rather than compliant behavior, becomes a prominent part of dealing with powerful adults.

During this era a very significant process may occur called the "malevolent transformation," which has serious consequences for future living. When this happens, because the situation may demand it, the child begins to think of himself as bad or unworthy whenever he feels the need for tenderness. In the boy, the need for tenderness is considered unmanly and weak. Therefore, he denies this need, which tends to evoke anxiety. At the same time, the possibility of interpersonal relationships of tenderness and warmth is made impossible since, when they are offered, they are strongly rebuffed. Tenderness is transformed into malevolence, and the child becomes surrounded by a sea of hostility which he can deal with only by hostile or paranoid rejoinders.

Juvenile era. When the child begins to manifest a need for compeers, which generally coincides with the beginning of formal education in Western culture, he has entered the juvenile era. Generally, this occurs when he is about 5 years old. Now his interpersonal range moves beyond his own home and his own parents. He must share a common parental figure in the form of a teacher and deal with other individuals who have equal claims upon her. He must learn to deal with new authorities and to cooperate, compete, and compromise with his peers. There is a great expansion of his self-system and an opportunity to correct earlier distortions because of the presence of new significant adults in his life. Behavior which might have been a source of rejection or disapproval previously may now elicit rewards which could modify his earlier reactions.

The development of the capacity for cooperation

and compromise provides the background for the competitive skill which is an important ingredient in his ability to face cultural demands in later life. During this period, the child develops a clear cut personality and characteristic ways of dealing with others. So far, he has had little experience with sex, except for some expressed preference for friends of the same sex. As the child enters preadolescence, friendships have begun to develop.

Preadolescence. This period, ranging from approximately 8 to 12 years of age, is notable for the development of the capacity for love and collaboration with another human being of the same sex. It is devoid of sexual exchanges, however, since gonadal maturation has not yet occurred. Firm friendships are formed, and loyalty, devotion, and sharing of feelings and closeness with another human being are much in evidence. This era was labeled homosexual by Freud because these relationships were between individuals of the same sex. However, Sullivan felt that the lust dynamism had not yet developed. It is only because people of the same sex are more like one another and therefore easier to understand, with common interests and desires, that these relationships occur. Such intimacies in the later periods of preadolescence may involve sex, but essentially they involve intimacy devoid of sex. One begins to see the world as one's compeers see it. Values are shared and mutual concerns and interests are aired. Self-appraisals are clarified and strengthened, and the possibility for favorable change is present since opportunities for tenderness and closeness are more available. One begins to consider the importance of other people's needs as well as one's own, which is the essential ingredient of a loving, tender attitude.

Difficulties begin to manifest themselves toward the end of the era, as the sexual apparatus begins to mature and friendships dissolve due to interest in the opposite sex. If there is unequal maturing or if one chum is, for some reason, unequal to the task of moving into heterosexual relationships, then there may be a clinging to preadolescent intimacy which may become complicated by lust, producing homosexual behavior. However, lust is a very powerful dynamism and generally succeeds in forcing most people out of the comfortable and successful preadolescent friendships which have been established. The tendency to label this era as a homosexual stage of development has produced grave mischief and grief with regard to the friendships and intimacies of people of the same sex. The cultural prejudices and proscriptions which derive from such a view often serve to discourage the development of tenderness, which is necessary in the heterosexual patterning which is to occur in adolescence.

Adolescence. This is a stormy period in human development. It is the crossroad between the dependent child and the independent adult, with all the complicated patternings of sex, vocation, and future

value systems still to be resolved. Even if one enters this period with a fairly solid self-system as an outgrowth of good earlier experiences, it is a most difficult transition. If, however, one arrives at this juncture with weak self-esteem and a tendency toward anxiety in interpersonal encounters, the transition to heterosexuality and adulthood will be extremely difficult. Intimacy with another human being is now complicated by lust, and the adolescent must overcome a great many previous restraints on nonlustful intimacies and try to establish sexual involvements as well. In addition, he must separate himself from his family dependencies at a time when he is not entirely independent either economically or emotionally. While still a boy, he is trying to be a man. He must decide upon a career and develop standards and values for the future. Compromises must be reached in accepting the values of the adult world. While he is struggling with all these issues, he is expected to be acquiring and perfecting scholastic or technical skills which will provide him with future economic security. It is a tumultuous period in which one seeks one's own identity as a human being. Now the interpersonal exchanges are confused and ambiguous, requiring the adolescent to make adult decisions while retaining a child's prerogatives.

When heterosexual patternings are established and adult roles are assumed, the period of adolescence draws to a close, and the individual has arrived at adulthood. However, adulthood is not always synonymous with maturity, which is achieved only by a fortunate few. Maturity involves a self-respect which permits one to meet most situations with a capacity for intimate and collaborative relationships and loving attitudes—an understandably difficult achievement.

The foregoing is a brief summary of the development of normal personality. A great deal more learning and experiencing than has been described here takes place during these stages. The limits of such learning are defined by the innate capacity of the individual, the interpersonal atmosphere in which it occurs, and the capacities and emotional integrity of the persons involved in these interpersonal relationships. In addition, cultural requirements and historical, political, and economic conditions also influence the developmental demands on the individual. Sullivan emphasized these factors, while he took into account the biological necessities which are so clearly manifested in infancy, childhood, and adolescence.

Psychopathology

While anxiety is the dynamic propelling force for personality development, it is also the essential element in the production of the neuroses, psychoses, and other psychopathological phenomena. The self-system, or dynamism, described earlier, develops in response to anxiety. The techniques and patterns of behavior comprising the self-system aim at alleviat-

ing and eliminating the distressing effects of anxiety. These security operations are rarely entirely successful, and inevitably the anxiety manifests itself in symptoms which can be noted in all human activity. Such symptoms comprise the bulk of psychosomatic complaints, ties, mannerisms, stereotyped behavior, activity in dreams, etc. They are devices for discharging tensions or minimal outburst of anxiety, without necessitating the breakdown of over-all adaptive patterns.

In this sense, the self-system, by discharging tensions in acceptable ways and preventing more massive outbursts of anxiety, maintains the individual as an effective functioning entity. However, under extreme stress imposed by external demands, or the overwhelming pressures of internal needs, the protective armor of the self-system is inadequate to stem the tide and more massive disintegration occurs, producing the neuroses and psychoses.

Sullivan's concept of mental disorder arises directly out of his interpersonal concepts. The self-system develops directly in relation to interpersonal needs or the need to avoid disapproval from significant adults. As noted above, in the early development of the self-system, certain experiences are personified in terms of the "good me," "bad me," and "not me." In the same way, individuals are personified as the "good" mother or "bad" mother, and this way of perceiving others is retained as a lifetime pattern, as highlighted in the transference aspects of the therapeutic process. The "not me" personification and often the "bad me" personification lie outside immediate awareness. Mental disorder results when some of these dissociated processes erupt into awareness. The nature of the disorder and diagnosis depend on the way the self-system maintains or fails to maintain itself in the face of these crises.

The neuroses. Sullivan distinguishes between the substitutive (neurotic) and the disintegrative (psychotic) processes. He believed that in the neuroses certain tendencies are dissociated; were they to manifest themselves in actual living, massive outbursts of anxiety and panic would result. They are dealt with in substitutive ways, particularly by the obsessional devices of distraction and displacement. These substitutive devices produce symptoms which combine to form a syndrome and are given a particular label. For example, in the obsessional neuroses, the profound insecurities of the individual are held in check by the substitutive devices of magic and control through ritual. In hysteria, the major substitutive technique is a simple process of amnesia in which clear recognition of issues is avoided and somatic substitutions become the major area of relating to others. Sullivan did not concern himself with the conventional, nosological categories; therefore he did not describe the neurotic disorders under the traditional classifications.

When the process of substitution is used, in order to

maintain anxiety at a tolerable level, the individual uses other techniques as well, such as sublimation, which may be broadly defined as a way of making unacceptable impulses acceptable. In addition, there is the ubiquitous tendency toward selective inattention, in which aspects of experiencing that might upset or stimulate anxiety are simply not noticed. As pointed out earlier in this section, if this technique becomes too extensive, it may seriously impair perception and learning and be responsible for many major deficiencies in functioning. It may become the basis for considerable distortion in the perceptual process.

The elements of a neurotic process consist of personality devices or techniques, the function of which is to keep out of awareness those responses, reactions, and impulses which, if admitted to awareness, would produce serious personality disorganization. The neurotic symptom, therefore, is an adaptive reaction, the major function of which is to prevent disintegration of personality and promote repair. Sullivan's view of the obsessional disorder gives one a clear notion of his concepts of psychopathology. He studied this disorder in great detail, and it was his work in this area that led to his examination of the schizophrenic process.

Freud viewed obsessive symptoms as a compromise attempt to deal with ambivalent feelings and to prevent the expression of unacceptable aggressive or sexual impulses. The symptom, as he saw it, was not only a displaced substitute for the impulse, but also a partial satisfaction of it. Sullivan, on the other hand, viewed the obsessional process as one in which the individual attempts to exert maximal control over himself and the universe, in order to guarantee and protect himself against deep feelings of uncertainty and insecurity. He attempts to do this by the personal magic of compulsive ritual or obsessive, ruminative omniscient thinking. And he strives to achieve perfection, omnipotence, and omniscience so that he may be beyond criticism, rejection, or danger. He avoids commitment and involvement, since these contain emotional elements which cannot be controlled. Most obsessive symptomatology can be understood in this framework.

The somatic disorders which frequently accompany obsessional states are the result of the inner tensions produced by these neurotic demands. Sullivan believed that there is very little outlet, even in dreams, for dissociated impulses in the obsessional states; therefore, there is a constant need for control in order to avoid the feeling that one might explode.

The psychoses. When the dissociated impulses actually do go out of control and the self-dynamism fails to retain its integrative capacity, psychosis results. Since Sullivan was primarily interested in the schizophrenic disorders, he focused very little of his attention on the clarification of the affective psychoses.

Psychosis results when the repressed aspects of personality emerge into conscious awareness. These aspects are alien to the ego and disruptive to the usual, conventional, acceptable social processes, and they evoke a sense of loathing and shame. Consequently, their manifestation produces a violent reaction which results in panic. This is frequently followed by the disintegration manifested by an extremely regressed catatonic reaction. In this state the individual withdraws from reality and becomes wholly preoccupied with fantasy, in a cosmic struggle that usually consists of intense rage, stuporous immobility, or a combination of both.

The acute catatonic reaction is generally followed either by resolution of the conflict or by the development of more severe and chronic personality reformulations. The resolution of the conflict and a reintegration of the self-system are possible either through an alteration of the circumstances which led to the disintegration, or through a lessening of the demands on one's psyche. The crisis can then be overcome, and the individual can return to his former way of life, albeit with some minor alterations. If, however, the individual attempts to reconstruct or reintegrate his self-system by repressing all doubts about himself or by bolstering his inadequate self-system by invalid referential processes, he may then experience a paranoid reorganization of personality. In this solution to a schizophrenic disaster, the individual achieves some security and certainty by restructuring the world in "manageable" ways, even if they are viewed as hostile or unfriendly ways. This solution often closes off any therapeutic possibility, unless doubt can be introduced into the self-contained and self-consistent paranoid system.

However, there are other possible solutions as well. Instead of an intellectually organized solution, such as the paranoid formulation, there can be a hebephrenic dilapidation in which emotional deterioration seems to be central. The individual gives up any attempt to view the world in coherent, systematic terms, and it becomes a totally illogical and meaningless world. Exchange and relationships are made impossible because of his determined effort to ward off involvement.
